Office, police, and most of the large railways submitted to medical examination before employment, consequently only a few were chosen out of many applicants. The remainder returned to the factories and workshops, where they were allowed to develop their diseases without interference. Slight hernias became uncontrollable by truss, necessitating an operation and financial loss to all concerned. Varicose veins produced ulceration and eczema, especially among laundrywomen and others who stood at their work. Enteroptosis in women, with all its consequent evils, caused misery and incompetence to thousands. These, together with boiler-maker's deafness and glassworker's catarrh, were a few of the evils which might be avoided. Medical inspection of employees threw light on industrial fatigue, which was a great handicap to the financial success of business, as it was useless to employ even skilled men for too many hours at a stretch if fatigue stepped in and Nature conquered man. The years 1914 to 1918, when almost all men were examined for various kinds of national work, showed the enormous amount of ill health that existed in the nation, and much discussion followed as to how a C3 population could become A1. In Mr Walker's opinion medical control was the only solution of the problem, it was doubtful if the expense incurred would not be more than compensated for by factories and workshops being filled with strong, healthy, and willing workers. More unrest, he believed, was caused in the industrial world by poor health and uncongenial surroundings than by low wages and all other reasons combined.

MODERNISM IN MEDICINE

THE first meeting of the new session of the Newcastle-upon-Tyne and Northern Counties Medical Society was held in the Royal Victoria Infirmary, Newcastle, on October 8th with Dr. NEIL MACLAY in the chair.

Dr. Maclay delivered his inaugural presidential address on modernism in medicine. As an observer of medical life for thirty years he had been able to view it from two different standpoints, first, as a general practitioner, and later from the somewhat narrower sphere of a specialist. This had been a period of great changes and advances in medicine, but nevertheless there were disquieting signs of retrogression. On all sides there was a steady growth of superstition, both in religion and medicine, and an inclination on the part of the public towards quackery. Dr. Maclay went on to deal with the part which medical men might play in combating these influences. The crowded curriculum of the student intensified the difficulties. As a result newly qualified men seemed to be now less able to judge what was commercial quackery and what scientific truth. It was required that throughout their careers there should be a desire for thoroughness in their work if they were to withstand the tendency towards shoddiness and flimsiness. In conclusion, the effect of the National Insurance Act was touched upon. The address was eagerly followed and appreciated by the audience.

Clinical Demonstration

There followed a demonstration of clinical cases. Mr J. S. ARKLE showed various ophthalmic cases, the chief of which were (1) a woman of 24 seven months pregnant, with a recent extensive haemorrhage into the vitreous, (2) ruptured choroid following concussion, (3) a severe neuroretinitis, with well marked "star" figure at the macula, in a patient without any obvious cause. Mr JOHN CLAY showed a man, aged 36, from whom he had removed an anastigmas sixteen years earlier after an injury, since then the man had been able to serve as an infantryman in the army and pursue heavy work regularly. Dr HORSLEY DRUMMOND showed a case of rotic aneurysm with dislocation of the inner end of the clavicle, also cases of mediastinal tumour and subacute combined degeneration of the cord. Dr GAVLEY demonstrated various radiological films. Dr W. E. HUME showed a case of erythraemia in a man of 48, in whom the symptoms had started six months earlier with haemoptysis, also cases of crossed paralysis from pontine softening and aneurysal fibrillation treated with quinine sulphate. Mr C. G. JAWYER showed a case of extensive syphilitic osteitis of the skull which appeared

the section dealing with innocent conditions (in the latter Lockyer's views are misquoted). In the section dealing with malignant growths the main feature is the treatment of carcinoma of the cervix with special reference to irradiation, and much food for reflection is provided by the statistics quoted. The toxæmia of pregnancy receives a whole chapter to itself. It is a discussion of theories rather than of concrete knowledge. The author hopes that the long-awaited discovery of the cause will be made in the next decade, by extended research into the neglected field of the endocrines. After this preliminary *faux pas* the author recovers himself and proceeds to deal with the incidence of the disease, quoting the report of the British Congress of Obstetricians and Gynecologists of 1922, with Edens's comments thereon. Stroganoff's report of his methods is given in full. The complications of pregnancy, with which this subject might have been combined, are dealt with in a separate chapter which incidentally is quite one of the best in the book. The metabolism of pregnancy and the chemical test supposed to indicate abnormalities of metabolism, with special reference to the onset of eclampsia, as presented by Berkeley and his associates, receive two or three pages which contain full information. The author unfortunately refrains from any criticism of his own on this subject. The views of Cook, as set forth in the Hunterian Lecture, are then stated, and the author says the greater part of the available evidence does not support his contentions. Most of the other complications of pregnancy are briefly reviewed and the information thereon brought up to date. The chapter concludes with a summary of FitzGibbon's lectures on pelvic contraction and its treatment. The volume closes with a chapter by Rubin on transuterine insufflation to determine patency of the Fallopian tubes. One would have expected to find this in the chapter on sterility, rather than in one entitled "Symptoms in Gynecology." In a composite work of this kind the lack of an editor is perhaps bound to be evident, and that is the chief complaint against an otherwise excellent volume, which can be heartily recommended to all who wish to bring their knowledge up to date. The reviewer closed the book wishing there had been more.

DENTAL INFECTIONS, ORAL AND SYSTEMIC

The purpose of the two volumes published under the title *Dental Infections, Oral and Systemic* is, the author, Mr. Weston A. Price, tells us, to present new data and important new interpretations suggested by them. It is, he says, the result of twenty-eight years' work on the part of himself and a staff numbering seldom fewer than five, and latterly as many as sixteen; the research work has, he adds, cost over 250,000 dollars, and he expresses deep regret that "so much of his energy had to be expended in the business side of dentistry in order that means might be available for conducting investigations, that time and strength were wanting to perfect these volumes to a greater degree." Mr. Price acknowledges himself an iconoclast, and he tilts vigorously at all forms of dental sepsis. Especially he condemns the indiscriminate preservation of "dead" teeth without reference to the patient's powers of resistance.

Mr. Price accepts the view that a streptococcus is responsible for practically all the evil results of dental sepsis, but attaches more importance to the "soil" than to the strain of streptococcus present. Thus he would classify humanity according to their susceptibility to the "rheumatic group of affections" into "insusceptibles," "susceptibles" (by inheritance), and "acquired susceptibles" (through "overload" of illness, worry, etc.), he thinks these classes can be differentiated, not only clinically, but by differences in the tonic calcium and the alkali reserve of the blood. He claims to show that people who suffer from dental caries are susceptible to the "rheumatic group of affections," while those who suffer from "pyorrhoæa" are insusceptible, he supports his conclusion by reference to the supposed incompatibility of

dental caries and pyorrhoæa—an incompatibility which by no means everyone acknowledges. Perhaps the most striking of Mr. Price's new interpretations is in connexion with bone reaction as shown by x-ray pictures. An area of rarifying osteitis is to be taken as an indication of vigorous reaction, even of safety, in areas of sclerosing osteitis is to be taken as an indication of poor local reaction and of the possibility of remote infection. We may remark that after reading the author's very capable presentation of the pitfalls of x-rays we are a little surprised at the extensive use he makes of x-ray pictures to support his case. But the author is fully aware that his ideas will be met by opposition, and we will leave it to the reader to form his judgement.

What will meet with more approval than he anticipates is his insistence of the danger of dead or infected teeth. He has devoted a large amount of experimental work to demonstrating these dangers. Using rabbits, he shows how potent for evil a single, apparently harmless, dead tooth may be, or even the cement from under an ill fitting gold cap. Not only cultures were used in the experiments, whole teeth were crushed and injected, or teeth were buried entire subcutaneously or in the peritoneal cavity, and from large numbers of these experiments the author draws valuable conclusions as to the dangers of dental sepsis. He finds in them some support for the idea of selective localization by a particular strain of streptococcus, but thinks this property was impressed on the germ by the previous host, and soon dies out.

In Volume I the author propounds some forty odd problems connected with dental infections. These problems range from the particular (for example, What are the dominant etiological factors in dental caries?) to the general (for example, Do dental infections produce sensitizations of an anaphylactic character?), and both questions and answers give evidence of a wide outlook and an acutely inquiring mind. Perhaps with the lapse of years some of the problems and some of the answers are no longer new, but there is always a refreshing disbelief in the old mechanical view that the whole duty of the dentist is to provide teeth to eat with.

Volume II is devoted to a review of the results of applying the new principles to everyday work, and contains an account of many interesting clinical cases and observations. From about two thousand cases the author has selected the most opposite and remarkable, with the inevitable result that some of them are almost startling in their sequence of cause and effect. Perhaps the most startling is that recorded in Volume I (p. 437), in which expanding the maxillary arch, with undoubted separation of the maxillary bones, was accompanied in twelve weeks, in a boy of 16, by all the phenomena of growth and adolescence which normally take years to develop, and were lost again with the loss of the apparatus used in the course of a few days. We cannot agree that hemophilia is in any sense a result of dental infection, and we think the author has made his observations on suppurating dental cysts, and so has been led to incriminate dental cysts as potent factors in dental infection.

The illustrations are numerous and well produced, but, especially in the case of the dissections showing lesions of rabbits' spines, would benefit by more extensive legends. The great fault we have to find with the book lies in the intricacy of the author's diction, which often leaves the reader in doubt, and now and then seems to be meaningless.

The author's whole heart is in his work, and his last chapter is an able exposition of the need for dental research institutes, and we most heartily echo his plea for endowments which will enable investigators to live for and by their work alone.

MEDICAL OPHTHALMOLOGY

It is not surprising that within the short space of three years a new edition of Mr. Foster Moore's *Medical Ophthalmology* should be required. As a connecting link between the specialized science of ophthalmology and the wider scope of general medicine it is unsurpassed in our

* *Dental Infection, Oral and Systemic*. By Weston A. Price. D.D.S. MS. F.A.C.D. Vol. I. *Factors on Fundamentals of Oral and Systemic Infection of Dental Infections*. Vol. II. *Researches on Clinical Infection of Dental Infections*. Cleveland Ohio. The Fenton Publishing Company. 1924. (Imp. 8vo. Vol. I pp xxvii + 675. 252 figures. Vol. II xxv + 411. 239 figures.)

* *Medical Ophthalmology*. By R. Foster Moore. O.B.E. M.A. B.Ch. Cantab. F.R.C.S. Second edition. London. J. and A. Churchill. 1925. (Demy. 8vo. pp. x + 34. 92 figures. 8 plates. 18 net.)

literature for its conciseness and clarity and its wealth of detail.

The subject-matter has been largely rearranged, several inconsequent articles have been deleted, and much new material has been incorporated. The whole of the text has been brought up to date, and new articles added on intracranial aneurysms and subarachnoid haemorrhages, on encephalitis periauricularis, tumours of the optic chiasm, retinoblastoma, jaundice, juvenile and adolescent forms of haemorrhagic degeneration, and the mechanism of the cerebri-maculal degeneration, the sections dealing with the normal pupillary reactions, the sections dealing with the defects of the visual fields have been much amplified, and are especially worthy of note.

While the references to the literature are full, a large number of the opinions expressed and of the observations recorded are drawn from the author's own experience, and these are given always in a shrewd and critical spirit. Thus the subject of ocular headaches, which encourages discursiveness, and the somewhat vague factors of focal infection and intestinal toxæmia, so often and popularly ascribed to as of greater or less importance in the etiology of ocular disease, are dismissed as being incapable of consideration with scientific and critical exactitude. This same spirit of discrimination is maintained throughout.

The book is well got up and well indexed. The numerous illustrations are of high standard, and have been increased in number, the additions including eight coloured plates.

AN INDEX OF TREATMENT

THE *Index of Treatment*, by Dr ROBERT HUTCHINSON and Mr SHERRER of the London Hospital, continues its triumphal march, for it has in eighteen years reached its ninth edition, and in the process has, like a snowball, increased mightily in size and in scope. As it is arranged in alphabetical order and well provided with cross references, the busy practitioner can at once put his hand on the information he seeks. The only disadvantages—and they are necessarily due to its success—are its very considerable weight, which makes it difficult to read in an easy chair, and its price. The senior editor, who has been responsible from the start of this popular work, contributes a wise introduction on some general principles of therapeutics, and quotes Clough's "Latest Decalogue" to the effect that while "Thou shalt not kill," we need "not strive officiously to keep alive." At this stage in the life of the population no criticism of details is necessary. In addition to a number of articles on the digestive system, he has a few words to say on nose (redness of), finger cracks, and prænæsthesia. Mr James Sherran, among other duties, provides the surgical treatments of the gastric disorders dealt with by his co-editor. Dr Luff writes fully on gout, and from Professor Hugh Macleod we welcome an infective endo-arteritis on nephritis. In a new article on immunized arthritis Dr Thomas Horder cautiously recommends a new article on arthritis sensitized by the serum of an article on poison. Sir Henry Gray contributes a new account of the surgical treatment of tuberculosis, with an account of hydrotherapy and artificial light treatment, spinal analgesia appears for the first time in a clear and well illustrated article by Dr F S Rood.

LIVING ORGANISMS

PROFESSOR EDWIN GOODRICH's little book, *Living Organisms*, is an excellent introduction to the doctrines of organic evolution. Professors of zoology are not always easily understood when they address themselves to a public not trained in biology, but Professor Goodrich has proved that the scientific point of view on life can be described in language everybody can follow. The interesting story he has to tell is not encumbered with technicalities and yet omits nothing that is necessary to the thread of the argument.

An Index of Treatment By Various Writers. Edited by Robert Hutchinson M.D. FRCP and James Sherran CBE FRCS Ninth Edition revised and enlarged. Pp (xii + 1035) 42 illustrations. 42s. (Rev. 8s 0d pp xvii + 1035 42s net) 1925 (Living) Organisms By Edwin Goodrich FRCS Oxford The Clarendon Press 1924 (Cr 8vo pp 200 60 figures 6s net)

We must begin, as in all similar books, with a chapter on the nature and origin of life, and close this chapter (as always) by clearing a patch of ground without building anything very substantial thereon. Before passing on to Darwinism and heredity, the main theme of the book, a good deal has to be said about the cellular structure of living organisms, their methods of reproduction, and the significance of death, and this is said clearly and simply. Once the main theme of the book has been expounded what follows is like the orderly working out of a plot—consecutive, logical, and inevitable. Thus we are led from a discussion of variation and the factors of inheritance to the struggle for existence and natural selection. The three final chapters are well placed, for they answer a good many questions raised by earlier pages. These deal with phylogeny and classification, the geological record of success and failure, and, finally, the evolution of intelligence. And so we come to the end, concluding with a thought which is likely to be present in the mind of the faithful reader (not, it is to be hoped, for the first time)—"Some knowledge of the chief results of the scientific study of evolution is indeed essential for the guidance of those who wish to promote the welfare of the human race on rational principles."

ANIMAL SOCIETIES

Des Sociétés Animales was written by ALFRED ESPINAS at a time when the minds of thinkers were largely occupied with sociological subjects, owing, to a great extent, to the writings of Auguste Comte. The book was a thesis for the doctorate in the Paris Faculté des Lettres in 1877, but a large part of the work was omitted from the first edition on account of certain apparently harmless references to Comte, which were regarded as obnoxious to the authorities. The second edition comprised the complete work, and the present, the third, was only very partially revised at the time of the author's death, so that the work practically retains its original form.

The object which Espinas set before him was to trace the connexion between sociology on the one hand and biology and politics on the other, to determine what is the binding force that unites separate individuals into societies, and to ascertain what general laws of social life may be deduced from the study of societies. As a basis of argument he has furnished the reader with analytical descriptions of the numerous and varied forms of social life that are met with in the animal kingdom, from the highest to the lowest, represented by the compound infusorians to the lowest, represented by the compound infusorians. These descriptions form a large, and perhaps the most interesting, part of the book. The conclusion at which he arrives as regards the binding force of social aggregation is that it varies as we pass from the lower to the higher types. He conceives that in the former, as exemplified in Volvox and the compound mechanical way, by failure of separation of the individuals resulting from the division of a single ovum. Certain advantages, difficult to detect, may be presumed to have resulted, which tended to perpetuate the connexion. In the next group, the compound Coelentera, the advantages are more distinct. In these, the group which, as in the former case, is derived from a single ovum, is formed of individuals organically united by means of intercommunicating channels between the body cavities subserving the function of nutrition. Here nutrition forms the bond of society, and Espinas calls such forms "societies of nutrition."

The second essential necessity of existence, reproduction, appears as a bond of union in those subdivisions of the animal kingdom in which the sexes are in separate individuals, but in this case the individuals are based on mutual attraction and choice, that is to say, a psychological element is introduced as an important factor in cementing the association. It is in the conjugal and domestic societies, according to Espinas, that there become developed the qualities of sympathy, domination, and subordination, which form an essential foundation for the highest social forms.

Des Sociétés Animales Par Alfred Espinas 1924 (Demy 8vo pp 454 25 fr) Paris F Alcan

Tenth edition.

form, the "peuplade," or people. The author holds that a highly organized domestic society is unfavourable, or even antagonistic, to the formation of a people, and cites instances where the latter arises only on the temporary dissolution of the families, disappearing when the families are reformed. It follows almost as a corollary from this that the formation of a people rests largely with the younger and unmarried individuals of a society, and Espirou solves the problem of defining the bond which unites a number of independent persons into a definite social entity by supposing that the conditions of environment come largely into play in these higher forms, and that by developing under like conditions the individuals develop like sentiments and inclinations. The bond will therefore be to a great extent purely psychical, but at the same time the habits of subordination and domination, as in the frequent instances met with of a tendency to act under a leader, and the sentiment of sympathy developed in the stage of domestic society, will also exercise a powerful influence. The political and moral deductions to be derived from the studies of animal societies would dwell with in, perhaps, a less interesting manner, but an interesting historical account is given of the theories of sociology from those of ancient Greece to more modern times.

NOTES ON BOOKS

ROGET'S *Thesaurus of English Words and Phrases* is, we imagine, too well known to need description, for it has been a valued reference book to generations of writers and translators and the vogue of cross word puzzles seems to have introduced it this year to large numbers of people, young and old, whose interest in literary craftsmanship is far from professional. The author, PETER MARK ROGET, M.D., F.R.S., physician and savant (1779-1869), after he retired from professional practice in 1840, devoted much thought and labour to compiling this work, which he had projected many years before it appeared first in 1852, and during his lifetime 25,000 copies were printed. An edition of 1879, embodying the author's latest corrections, was edited by his son, John Lewis Roget, who continued to revise periodical reprints until his death in 1908. In 1910 a grandson, Mr SAMUEL ROMILLY ROGET revised and added to the work, and a further edition has now been issued under the same editorship. This contains some 2,000 additional words and expressions, and the type has been reset throughout. The novelty of Peter Mark Roget's method of classification lay in his arrangement of words and idiomatic combinations, not in alphabetical order as in a dictionary, but according to the ideas they express, and this plan, so helpful to the literary workman bothered for the right phrase, has been preserved by the author's son and grandson through successive editions. The copious alphabetical index, without which the *Thesaurus* would lose much of its usefulness, appears to have been revised and amplified with the same care that has been spent upon the body of the work.

In his brief but brilliant book *Idiot Man*¹⁰ Professor RICHET, the physiologist, who has just resigned his chair in Paris, finds no difficulty in collecting a thousand follies of mankind and proving that this world is an ill regulated affair and capable of vast improvement in every business that concerns human beings. On all sides he finds evidences of their stupidity, their inability to learn, their lack of power to foresee the consequences of their actions and policies. He would have us believe, on the strength of scores of examples he has collected, that animals show much better reasoning faculties than man, to have reason, and he as unreasonable as mankind so often is, is much worse, he argues, than it is to lack the faculty of reason. Every page of the volume is filled with paradoxes of the first water, the whole makes excellent reading, and the book, for all its multitudinous extraneousness, may be commended to the attention of all readers in search of a rousing

Dr H. LAUBER has edited a rather big book¹¹ of medical advice on the choice of a profession, consisting of eleven

articles written by Vienna specialists. The editor himself contributes the chapter on the choice of a profession from the ophthalmological standpoint. The first three chapters, which attack the mental aspects of the problem from the standpoints of the psychologist, alienist, and specialist in mental defects, are written by Dr Rudolf Allers, Professor Erwin Stransky, and Dr Irwin Lager. Professor E. Jähle, who discusses the question from the pediatric standpoint as well as from that of internal medicine, emphasizes the importance of taking into consideration chronic disorders and intercurrent diseases as well as the constitution and disposition of the subject. Dr Gustav Alexander, who deals with otological aspects, lays stress on the value of medical inspection in schools not only for the individual, but also for the community. His article contains alphabetical lists of various professions with the amount of auditory function required in each, and of occupations suitable for persons with different grades of defective hearing. The remaining articles in the volume deal with laryngology and rhinology (Dr Hermann Marschik), surgery and orthopaedics (Dr Hans Spitzly), and neurology (Dr Ludwig Dimitz). An alphabetical list of professions is appended, with the ophthalmological and otological requirements pointed in italics and the contraindications for each profession in roman type.

Koby's *Slit lamp Microscopy of the Living Eye* has lately been reviewed in our columns (May 23rd, 1925, p. 971), the high standard it attains and its value as the only simple and compact textbook on the subject suitable for a beginner was then pointed out. It is now accessible in English,¹² the task of translation having been undertaken by Mr C. GOULDEN and Mrs C. L. HARRIS. Every language has its own genius—an individualistic quality nearly if not quite impossible to reproduce with any degree of success in any other language. In the endeavour to retain faithfully the exact shade of the author's meaning, it is easy for the translator to sacrifice the spirit of his own language by forcing upon it the mould of another. By a literal word for word translation the crispness and idiom of French composition becomes in English stilted, and, when sustained, forms somewhat trying and difficult reading. Although the translators have not avoided these faults they have certainly filled a serious blank in our ophthalmic literature.

HEINZ LINNEKEGEL has devised a method of treating tuberculosis with inhalations of a mixture of calcium sulphate and silica,¹³ which he calls "casi." He starts from the fact that gypsum workers and others exposed to chalk dust are believed to have a distinct immunity to tuberculosis. He claims that his inhalation method has shown itself successful in tests extending over three years. The use of silica in the inhalation is strange, since most of the evidence available indicates that the presence of silica in tissues facilitates the growth of the tubercle bacillus.

SOCIETY OF MEDICAL OFFICERS OF HEALTH

PRESIDENT'S ADDRESS. METHODS OF PREVENTION IN DIPHTHERIA AND SCARLET FEVER

The annual general meeting of the Society of Medical Officers of Health was held on October 16th, when Dr G. F. BUCHAN, medical officer of health for Willesden, was installed as president.

Dr Buchan took for the subject of his presidential address "Methods of prevention in diphtheria and scarlet fever." He exhibited a table showing that the total number of deaths and the death rates from diphtheria in England and Wales had not materially changed during the last half-century. The death rate per 100,000 persons living was 10.8 in 1873 and 10.7 in 1922 (though the years 1923 and 1924 showed a rather striking reduction). The total number of deaths and the death rates from scarlet fever had gradually and progressively diminished (the death rate, which was 85.1 in 1875, was 2.3 in 1924). Unfortunately, it was not possible to give the number of notifications of these diseases over the same period, but since 1911 it was evident from the records available that there had been no

SOCIETY OF MEDICAL OFFICERS OF HEALTH

THE BRITISH MEDICAL JOURNAL

real duration in the number of cases of diphtheria or scarlet fever. The number of diphtheria notifications per 1,000 of the population was in 1911 1.33, and in 1924 1.08. The corresponding figures for scarlet fever were 2.90 and 2.18.

These notification returns suggested that the methods in vogue for the prevention of diphtheria and scarlet fever had not met with success. These methods were hospital isolation, disinfection, quarantine of contacts, and general improvement in sanitation. Hospital isolation and treatment had been effective in reducing the number of deaths from both diseases, but not in preventing spread. Cases were not as a rule seen by the doctor until at least twelve hours after onset, by which time other poisons had been exposed to infection, therefore it was not to be expected that removal of the case to the hospital could act as an effective barrier against the spread of the disease. Dr Buchan also gave reasons for believing that the methods of disinfection in general use—spraying of rooms with formalin and removal and steam disinfection of bed and clothing—were without influence in preventing the spread of diphtheria and scarlet fever. He judged the value of disinfection by the proportion of secondary cases which occurred afterwards. From some Willemsen experience of the varying relative values of these methods of disinfection under conditions as strictly comparable as it was possible to obtain in practice, and especially from the fact that the addition of steam disinfection to spraying by formalin, and vice versa, appeared to increase the infectiousness of rooms and bedding in scarlet fever as judged by the percentage of secondary cases, he concluded that disinfection, as commonly carried out, was without influence in prevention. Quarantine of contacts, again, could never be satisfactory, because it was practically impossible to isolate children while they remained well. As for general improvement in sanitation, this measure was not specific against infectious diseases, though in so far as it improved the general health it was a preventive measure against all diseases, infectious or otherwise. He examined the common explanation that "missed" cases explained in only a small part the continued prevalence of "Carrier" cases greatly increased the difficulties of control in both diseases, and might indeed be a source of their regeneration and continuity.

The daily supervision of contacts and continuity with immediate administration of antitoxin on the first appearance of symptoms, was likely to prove an effective means of prevention, but it would be impracticable in many cases, and routine prophylactic injection of antitoxin for diphtheria contacts could not be recommended. The Schick test offered itself as a means of separating the susceptible from the immune. This test, followed by immunization, had been demonstrated by reliable scientific observers and clinical workers as a means by which the prevalence of diphtheria could be reduced by 75 per cent. The test had been used in over 125,000 cases of school children in New York with no ill results, and experience in Edinburgh, Birmingham, and Bristol had also shown the value of the test. He urged that this method, at present offered to the public by certain health departments, should be available everywhere.

With regard to scarlet fever, the conditions were somewhat different. Here the organism had not been isolated in the same way, but there was a consensus of medical opinion that streptococci had a definite relationship to the condition, and that a type of streptococcus giving specific agglutination and immunity reactions could be isolated from the throats of nearly all early cases. The Dick test of immunization for scarlet fever had not been so extensively applied as the Schick test for diphtheria and it was impossible to speak with the same conviction of its merits. But investigations showed that it was possible to immunize effectively against scarlet fever, with a large reduction of cases amongst the persons so immunized. It might therefore be urged that the Dick test, with immunization of some modification thereof, should also be made available in this country for those who would secure protection for their children against scarlet fever.

In conclusion, Dr Buchan said that of the annual expenditure on hospitals for infectious diseases (about

£3,640,000) at least £3,000,000 represented expenditure on diphtheria and scarlet fever, and that the general use of the Schick test and the Dick test, followed by immunization would reduce this expenditure by 50 per cent. To carry out this work effectively there should be in each area having a population of 100,000 or more an epidemiologist whose primary duty would be the application of the tests and immunization in the case of all children for whom the parents desired immunity. This officer would also be charged with the duty of intensive study of the occurrence of infectious diseases in the area with a view to the reduction of their prevalence by the application of laboratory findings in the field.

Annual Dinner of the Society

The annual dinner was held at the Piccadilly Hotel on the same evening, when Dr G. F. BUCHAN presided over a gathering of 180 members and guests.

Sir H. KINGSLEY WOOD, M.P. (Parliamentary Secretary to the Ministry of Health), in proposing the health of the society, said that its relationship with the Ministry was most cordial. The Ministry wished in particular to thank it for the work it had done in connection with the international interchanges of health officers and the demonstration to officers from abroad of British public health methods. He emphasized the need for further medical research in connection with public health—without, however, pledging any financial assistance—and also said that one of the most desirable things at the moment was the linking up of miscellaneous health agencies in each locality. At present in each administrative area there were about nine medical officers or units with different functions, and co-ordination was badly needed.

Dr BUCHAN, in responding to the toast, said that the society had now nearly seventy years of history. During the period of its existence it had seen all the gross cruises of ill health removed, and now, in order to increase longevity, it was necessary to work intensively on the causes that remained. This implied study and research and the application of the findings of research in the areas of local authorities. If progress in public health was to continue and be accelerated it would be necessary for local authorities to take an interest in preventive medicine. The elucidation of the problems of the future must be based on the conception of prevention rather than cure of disease. The speaker was of opinion that an undergraduate medical student should not be able to receive his medical degree unless he had had some opportunity of inspecting and reporting on the medical work which was done by his local authority, so that he might understand the trend of modern public health in relation to his future practice.

Dr W. J. HOWARTH proposed the toast of "The Guests," and mentioned the names of several well known people present. He regretted the absence of Dr Bolam, Chairman of Council of the British Medical Association, but he was glad to see present Dr Brackenbury, Chairman of the Representative Body, and Dr Cox, Medical Secretary. When Dr Bolam and Dr Brackenbury ceased to run in double harness it would be a bad thing for the British Medical Association, and perhaps for the Society of Medical Officers of Health also.

Sir ALFRED MOY, M.P., in responding, said that recently he had had some acquaintance with the public health work on the Continent, and he came back all the more appreciative of British methods, especially in regard to maternity and child welfare. One curious impediment in the way of the public health reformer, as illustrated recently in the East End of London, was the resistance of the people to whom it was desired to provide something better than the slum dwellings. He also referred to the new School of Hygiene and Tropical Medicine, which was now being put into a practicable scheme, and he hoped soon to see the commencement of the building. He believed that its influence upon public health would be very far-reaching. Sir ARTHUR CHURCH, chairman of the County Councils Association, also responded to the toast, and a further response was made by Sir ST. CLARE THOMSON, President of the Royal Society of Medicine, who, as usual, had a budget of excellent after dinner stories.

British Medical Journal.

SATURDAY, OCTOBER 24TH, 1925

HEREDITY AND MENTAL DISEASE

THE subject chosen by Sir Frederick Mott for his Harvard Oration, which is published this week (p. 727), is of fundamental psychiatric importance. The influence of heredity in the development of many psychotic conditions is one that cannot be set aside, but at the same time the existence of this factor should not be made the excuse for a despondent and fatalistic attitude in regard to the possibilities of prevention, amelioration, and cure of the variety of illnesses included under the term 'mental disease'. On the contrary, the recognition of an inherent causal factor in certain forms of psychic abnormality should act as a stimulus for research—first, into the kind of parental defects of character, infections, or disease which may be responsible for the production of psychopathic offspring, and secondly, into the exact biological nature of the deficiency which is inherited in the predisposed subject. Sir Frederick Mott's work on dementia praecox, of which he gave a summary account, may, indeed, be described as a contribution of peculiar importance to psychiatry from the fact that it takes us beyond vague references to the constitutional character of this disease, and enlightens us as to the actual nature of the organic deficiencies responsible for its occurrence.

The conception of dementia praecox as the outcome of a vital defect of the reproductive organs, of the brain, and probably of the whole organism, raises a number of questions of importance. The regressive physical changes described are such as might be anticipated in view of the alterations in behaviour which the subjects of mental disorder exhibit. Kriepelin, indeed, did favour the view that there was some connexion between the functions of the sex glands and dementia praecox, having in mind, no doubt, the inadequacy of the sexual life of the subjects of this disorder, though he was unable to discover convincing proof in favour of this view. It is clear that the discovery of so clear a correlation between demonstrable changes in the organism and behaviour changes necessitates a widening of our concepts as to the nature of mental disease. Except for descriptive purposes it is obviously unprofitable to regard mind as an entity in itself and detached from the organism, and we must not indeed, expect to discover the secrets of mental disorder by confining researches to the brain on the assumption that the brain is the organ of mind. The mind is not merely a function of the brain; it is a function of the whole organism, having its roots in the viscera, the endocrine glands, the vegetative nervous system and the musculature. Such a point of view is essential for our understanding of human behaviour, whether normal or abnormal, and a recognition of this fact is evident in general psychology, in which there is an increasing tendency to emphasize the significance of the instinctive or organic life as the basis of conduct.

That temperament is independent of conscious experience is evident from Galton's inquiry into the

history of dissimilar and similar twins, to which Sir Frederick Mott referred. This inquiry showed that temperament and the raw material of character are inherited for it was found that identical twins brought up in different environments remained temperamentally the same and of the same disposition, whereas dissimilar twins brought up in the same environment remained temperamentally different. Our increased psychiatric knowledge should now enable us to carry such observations further than Galton was able to do. Thus, as the outcome of Kraepelin's formulation of the biogenetic psychoses into two main types—the manic depressives with a general tendency to exhibit emotional fluctuations in the direction of depression or excitement, and the precox types with a general tendency towards a progressive deterioration tilting the form of a regression into fantasy and a withdrawal from contact with real life—it became possible to recognize similar reacting tendencies in normal people and to divide humanity generally, as Jung has done, into extroverts and introverts respectively. This important psychological work has been independently carried a stage further by Kretschmer, who has correlated the extroverted (cyclothymic) temperament with a robust body build which he describes as pyknic, and the introverted (schizothymic) temperament with an athletic or asthenic body-build, together with certain dysplastic types such as are often observed in dementia praecox. An interesting confirmation of such views is to be found from observations on dissimilar twins, one of whom may exhibit the typical pyknic physique with a strongly extroverted temperament, and the other a typical asthenic body-build with a typically introverted temperament.

Thus there would seem to be a close connexion between physique and temperament in normal people, and possibly, if the whole organism is taken into consideration, between the functioning of the endocrine glands and temperament. That this is so in abucinal types is shown by Sir Frederick Mott's researches, and the problem arises as to how far the development of an actual psychosis is avoidable in subjects predisposed to dementia praecox owing to inherent weakness such as he describes. This problem permits of no decisive answer, but there would seem to be certain grounds for supposing that many severe breakdowns of the dementia praecox type might have been avoided had the significance and dangers of the schizophrenic personality been more generally appreciated and more care taken to avoid external stress. The shut-in type of child tends to react very unfavourably to an environment where it is not understood and its sensitiveness not realized. A nervous subject of this type will very quickly regress into a mild psychotic state in what to him constitutes an unfriendly and traumatic environment, and will readily regain his equilibrium upon his removal to a more favourable milieu. Many psychiatrists believe that the continual association of a child from birth with exacting psychopathic parents is in itself responsible for psychotic reactions later in life, but no doubt the inborn predisposition of body and mind is an essential element in such a case. Jung discusses a similar temporary reaction in the normal introvert, and points out that, given a thoroughly congenial and harmonious milieu, he relaxes and expands towards complete extroversion, until the observer begins to wonder whether he may not be dealing with an extrovert. In many cases the exciting cause of a breakdown is found in intense application and overstudy during adolescence,

causing overstrain of unstable cortical neurones. Again, as Sir Frederick Mott points out, through an inherent defect many persons are apt to fail to function at the critical periods of life—namely, adolescence, the climacterium, and senescence, in women the physiological conditions of stress—gestation, parturition, and lactation—are often exciting factors. Other traumatic factors are emotional stress, repression, and frustration of the sex instinct, causing endocrine disturbances and insomnia.

There would seem, therefore, to be certain directions in which precautions might be taken to prevent the onset of dementia praecox in predisposed subjects, and greater facilities for the treatment of mental disorder in its early stages may reasonably be expected to be of value in this way. That the degree to which the vitality is impaired in potential cases of dementia praecox varies very greatly is evident from the fact that many patients do not actually exhibit the characteristic symptoms of this disorder until the involutional period or even senescence sets in. Just as dementia praecox may occur at all ages, so it may also occur in various mild forms, and, as Bolton has pointed out, included in this category must be those individuals who overstrain their mental capacities in youth—both the brilliant student and the one of inferior capacity who obtains a degree by dint of exceptional perseverance—and who in after life fail to fulfil their early promise, and eventually lead an ordinary narrow and stereotyped existence.

In the actual treatment of cases of dementia praecox the question of heredity must obviously be purely academic. No quantitative estimation is possible of the extent to which a psychotic episode is due to inborn causes and to environmental conditions respectively. Many cases are the result of stresses such as have been indicated, or are due to the influence of general or focal infections, and treatment must obviously be directed to the removal of the conditions responsible for the outbreak of morbid dementia praecox by symptoms. The prevention of dementia praecox by preventing predisposed subjects from propagation is extremely difficult, and not enough is known of the laws of heredity to predict the likelihood of abnormal offspring. Many cases of dementia praecox result from the union of parents a psychiatrist would certainly have hesitated to advise not to marry. The eugenic aspect of this subject must always be borne in mind, however, when the advice of the physician is asked in regard to marriage. Strong reasons are obviously necessary to advise against taking this step, but the teaching of all psychiatrists, and in particular the researches which are outlined in this article, make it clear that an unfavourable family history should cause no couple to hesitate to take the responsibility of parenthood. It is much to be desired that a knowledge of the principles of mental hygiene may eventually become more disseminated, and that potential parents may realize the serious responsibility they undertake in bringing children into the world who are likely to be psychopathic in tendencies.

In concluding these few comments on the researches briefly outlined in the Harvard Oration, it would seem appropriate to refer generally to the value of Sir Frederick Mott's work and to the great influence he has exerted upon the development of psychiatry in this country. As a teacher original investigator, organizer of research and as a source of inspiration to younger psychiatrists he is fully deserving of the high regard in which he is held in the medical world.

PITUITARY ADENOMATA

"It is highly profitable at times for a chief of service to play the part of bystander and to see what interpretations younger and fresher minds may put upon matters on which he perhaps has somewhat fixed ideas." Such is the note with which Professor Harvey Cushing introduces a long paper by Drs. Dott and Bailey in the current issue of the *British Journal of Surgery* (No 50, October, 1925), founded on a study of numerous cases of pituitary disease. They have confined their attention to the adenomata, and from the wonderful material at the Bingham Hospital, Boston, placed at their disposal by Cushing, they were able to collect no fewer than 162 examples of this type of tumour, all but one removed at operation. As the result of careful clinical and pathological investigation they claim that they have been able to differentiate certain clear cut types of adenomata, and to link with each of them a distinct clinical syndrome.

The basis of classification employed was the presence or absence of those cells of the normal pars distalis which are so noticeable in properly stained sections by virtue of their avidity for dyes—then cytoplasm being filled with deeply staining granules. These are the chromophil or, more familiarly, the eosinophil cells, and 35 of the tumours examined appeared to be composed largely of these cells. Of the remainder 107 contained no granule bearing cells, and it is suggested that they take origin from the chromophobes—the non-staining cells of the pars distalis. The few remaining tumours were found to have a constitution which represented a mixture of the two cell types.

From an analysis of the clinical histories of the cases from which these tumours were derived the following types emerged: (1) Cases with no constitutional disturbance beyond local pressure signs, and these we may dismiss from further consideration, (2) those with the hypopituitary syndrome, (3) those with the hyperpituitary syndrome, (4) a mixed type. When the attempt was made to correlate the clinical syndromes with the pathological findings, it was found that a striking parallelism exists between the predominant cell type in the tumour and the constitutional symptoms.

Gigantism and acromegaly are both diseases about the diagnosis of which there can be no doubt, and in no fewer than 35 out of 39 cases of this type in which the diagnosis was identified. Hypopituitarism in cosmophil adenomata was manifested, particularly in its less dramatic manifestations, but in 107 cases the lesser degrees of the disease, but in 107 cases which showed some or all of such symptoms as adiposity, hypotrichosis, lowered basal metabolism, and sterility, in addition to the local signs occasioned by the tumour, there was a complete absence of the chromophobe or non-staining type. In 13 patients the symptoms were of mixed and varied type, slight signs of acromegaly appearing to develop concurrently with hypopituitary manifestations, and in these cases the histological character of the tumour reflected the clinical signs of the disease. In 13 types of cells were mixed in varying proportions.

If these histological and clinical relationships are as close as the authors suggest (and although we cannot review the evidence in detail here it seems probable they put forward a very strong case) it seems probable that their work forms a useful contribution towards the elucidation of the function of the hypophysis in relation to the physiology of growth. We know from Evans's experimental work on rats that gigantism may

b. induced and the dwarfism of post operative hypopituitarism relieved by the intraperitoneal injection of pars distalis. Where does the active principle controlling growth reside? The evidence afforded by demonstrating the presence in 35 out of 39 cases of acromegaly or gigantism of an adenoma composed almost entirely of eosinophil cells, indistinguishable in microscopic structure and staining reaction from the eosinophil cells of the normal pars distalis, does seem strongly to suggest that it is in these cells that the secrets of growth must be sought.

THE HARVEIAN FESTIVAL IN LONDON

THE HARVEIAN Festival of the Royal College of Physicians of London was celebrated this year on Monday, October 19th, because St Luke's day, on which it is usually held, fell on the previous Sunday. The first event was the attendance of the President of the College, Sir Humphry Rolleston, and the consorts at the service at St Mary-le-Bow, Chancery Lane, at noon. This is something of an innovation. Dr William Croone, a Fellow of the College, at his death in 1684, left a plan for two lectureships, and for a sermon at St Mary-le-Bow. Dr Croone, however, failed to make any provision for the endowment of these lectures, and his widow, who married Sir Edwin Sadler, Bt., carried out his intention by bequeathing in 1706 the King's Head Tavern in Lambeth Hill, after the decease of her second husband, in trust as to four parts out of five to the College of Physicians and the fifth part to the Royal Society. Hence the Croonian Lectures delivered to these learned bodies yearly, and hence also the visit to St Mary-le-Bow. The rector (the Rev. Gordon Penson, formerly chaplain of Trinity College, Cambridge) read the 44th chapter of Ecclesiastes—the chapter beginning "Let us now praise famous men"—and then delivered a sermon based on the life of Sir Thomas Browne, author of the *Religio Medici*. He reminded the congregation that Sir Thomas Browne was born, within sight of the steeple of St Mary-le-Bow, on that very day, October 19th, in 1605, and he died in 1682, also on October 19th, shortly after the present church had been completed by Wren. After quoting several passages from Thomas Browne's works in illustration of his wisdom, piety, and abundant humanity, the preacher went on to say that it was a matter for thankfulness that the supply of such men to English medicine and letters had never failed. The Royal College of Physicians itself had been remarkable for the number of men among its Fellows who had enriched other fields besides medicine, in particular the fields of classical scholarship and philosophy. During the present year the College had to mourn the loss of two men who in a special degree had carried on the tradition of Sir Thomas Browne. One of these was Sir Clifford Allbutt, with whom the preacher had had personal acquaintance. Clifford Allbutt was a man who had added greatly to the knowledge of medicine, but he was above all things a friend, a wise counsellor and an upright and kindly gentleman. The other was the late registrar of the College, Dr J. A. Osmered, a classical scholar of no small attainments, a man versed in the traditions of the College, one who was strong but without self-assertion, and who was held in high esteem as a considerate and unselfish colleague. Both these men were "sons of the mouse." But while he had singled out only these figures, the hall of the College was hung with the portraits of many such men. Truly it might be said of them, in the words of the ancient writer, "Their seed shall remain for ever, and their glory shall not be blotted out. Their bodies are buried in peace, but their name liveth for evermore. The people will tell

of their wisdom, and the congregation will show forth their praise." The next event was a meeting in the afternoon at the College to hear the Harveian Oration (published at page 727) delivered by Sir Frederick Mott. Afterwards the Baly medal was presented to Professor Rudolf Magnus of the University of Utrecht. The medal was founded by Dr F. D. Dister in 1866 in memory of William Baly, and is awarded every alternate year to the person deemed to have most distinguished himself in the science of physiology, especially during the two years immediately preceding the award. The work done by Professor Magnus and his fellow workers at Utrecht may be looked upon as parallel or supplementary to the work of Sir Charles Sherrington at Oxford. Speaking very generally, the researches have been concerned with the parts played in movements and posture by consciousness and the reflexes which do not rise into consciousness but act and control posture and certain movements which at first sight present all the qualities of conscious purpose. The point is illustrated by the case of a cat watching a mouse. The head of the cat is turned towards its prey and one forefoot is extended and carries the weight of the body, while the other is relaxed and ready to make the sudden movement. The decision to jump is determined by the animal's consciousness, but it acts through a set of mechanisms of which it would appear the animal is not conscious. The posture is due to a balance of tone between the muscles concerned, this tone in the standing or flexor muscles varies in harmony the one with the other. The maintenance of posture and its modifications is brought about by reflexes, each of which is parallel. An animal in which the whole brain has been severed from the spinal cord cannot balance itself, but many reflexes remain, and there will be a response to stimulation by appropriate movements. If, on the other hand, the posterior part of the medulla is left connected with the spinal cord the animal can maintain the upright posture through the action of receptors in the muscles themselves. If the separation of the brain is made higher up the standing posture becomes more natural. Thus, it appears, is due to the added action of receptors in the muscles of the neck and of the larynx, but these actions of these receptors, while they can control the lower reflexes, are automatic. Finally, in monkeys and man other receptors from the environment come into play, the chief of these come through the eyes, and have their seat in the cortex. Professor Magnus gave an account of his researches in his Croonian Lecture to the Royal Society last summer. The last part of the festival was the dinner in the evening, given in accordance with the instructions of Harvey when he handed over to the College his paternal estate of Bunnbury in Kent in 1656. The dinner was held in the College, and the President, Sir Humphry Rolleston, was in the chair. Among the guests were the Presidents of the Royal College of Surgeons, of the Royal Academy, and of the Royal Society of Medicine, the Master of the Society of Apothecaries (Dr Vincent Dickinson), the Hon. Sir Peter C. Lukin (High Commissioner for Canada), Professor R. Magnus, the Vice-Chancellor of Cambridge (Dr A. C. Seward, F.R.S.), and Sir Gilbert Buling, Vice-Chancellor of the University of Birmingham, where Sir Frederick Mott is lecturer on psychology. The President, in giving the toast of "The Guests," referred to the improvement the College had been stimulated to make in the appearance of its building by the great house-clearing next door, carried out under the supervision of the High Commissioner for Canada. The toast was acknowledged by Lord Lawrence of Kingsgate and the Master of the Rolls (Sir Finest Pollard). The toast of "The Harveian Oration" was given by Sir John Rose Bradford, senior censor, and acknowledged by Sir Frederick Mott in a general speech.

THE NATIONAL COLLECTION OF TYPE CULTURES

WE are glad to see that a second edition of the catalogue of the National Collection of Type Cultures has been issued.¹ The museum of cultures of bacteria, yeasts, and moulds has grown very considerably since it was founded five years ago, and in the three years which have elapsed since the last edition of the catalogue appeared many additions have been made to the collection. The number of living strains of bacteria, yeasts, and moulds now being maintained in cultivation exceeds 2,000. The National Collection of Type Cultures is particularly useful for two reasons. In the first place, it assures continuity in bacteriological research by preserving historic strains with which new cultures may be compared. Secondly, it serves as a storehouse from which any pathologist can, for a small fee, obtain any particular culture he wishes to study. This service satisfies a real need, as shown by the fact that over 4,000 cultures were distributed to workers throughout the world in 1924. The arrangement of the second edition of this catalogue is more convenient than that of the first. The first part gives a list of the cultures in alphabetical order. The second part gives a list of subjects and their related micro organisms. Thus, if we turn to food poisoning in man we find the names of seven different species of bacteria which are preserved in the collection, and the full name and a certain amount of detail about the origin of each culture can be found by turning to the alphabetical index in Part I. The fungi are always troublesome to label, and we notice that the nomenclature used for these is that which has been adopted by the British Mycological Society. It would add to the value of this catalogue if a little more information were given about the origin of some of the less familiar cultures, and in every case references given to publications in which the rarer cultures have been described. Such references are given for many of the cultures, but, oddly enough, references seem scantiest among types with least pronounceable names. To harvest this collection of germs must have necessitated an enormous amount of work. It is a most useful asset to science.

SCIENTIFIC AND INDUSTRIAL RESEARCH

THE report of the Committee of the Privy Council for Scientific and Industrial Research for 1924-25, to which brief reference was made in our last issue (p. 725), shows that its annual expenditure is increasing, in 1923-24 the estimates amounted to £276,863, last year to £328,281, and for the coming year to £380,263, all these figures including administrative expenses. They are evidence of a growing appreciation of the importance of scientific research to industry. This is exemplified also by the founding of a research association by the colliery owners in accordance with a scheme recommended by the Department of Scientific and Industrial Research, it is financed by a levy of approximately 1/100 of a penny on each ton of coal raised, no grant being required from the department. Proposals are being considered for the establishment of a Food Research Association, which it is anticipated will receive the aid of a grant. During the year the Glass Research Association and the British Portland Cement Association have concluded their operations. For the former association insufficient funds were forthcoming from the industry, but the Privy Council Committee has decided that the progress of the research work on the viscosity of glass at high temperatures should not be interrupted, nor the x-ray and electrical investigations of the constitution of glass which form part of the ordinary programme of the National Physical Laboratory. We referred on August 30th, 1924 (p. 374), to the work carried on by Sir William Bragg in connexion with the x-ray analysis of

crystals, and it is interesting to note that more than thirty papers have been published on this subject by Sir William and his collaborators during the year under review. The investigations undertaken by the National Physical Laboratory cover a very wide field, as we indicated last April (p. 750) when discussing its annual report for 1924. It may be added here that the work of the laboratory, which is under the supervision of the Privy Council Committee, includes test work in radiology and the inspection of hospital x-ray apparatus and departments. It is announced that there has been marked improvement both in this apparatus and in the protection afforded to operators. We have on several occasions referred previously to the work of the Food Investigation Board, of which Sir W. B. Hardy is chairman. Attention has been centred mainly upon the problems associated with the freezing of beef, the preservation of eggs, and the use of cold and carbon dioxide in the preservation of fruit. The freezing of tissues has been found to involve displacement of the water in them, which may result in a permanent alteration of their microscopic structure, and also in destruction of their finer molecular structure. The relative efficiency of "gas" and "cold" storage of fruit and the development of the fungi concerned in the rotting of fruit are also being carefully studied. A survey of the conditions of fish transport in this country and in France is published in a special report. Work is also proceeding in the laboratory on silver-tin amalgams for dental work, and at Guy's Hospital on substitutes for the materials now used in the preparation of dentures. In this latter respect synthetic products are being studied, and there is some promise of a satisfactory outcome.

DISABLED MEN AS MOTORISTS

IN the course of a recent correspondence in the *Times* on safe driving, there was published a letter from Mr. B. H. Austin, chairman of the Disabled Drivers' Motor Club. In it he pointed out the difficulty of having a definition of physical disability such as would debar a person from the right to drive a car. He said that some years ago he had undergone amputation of both his legs, but that nevertheless he covered an average of 20,000 miles a year in his car, and offered to drive a magistrate, who appeared to believe in physical tests for motorists, either through the City at muddy or at top speed he led at Brooklands. Mr. Austin drives his car in the ordinary way by means of his artificial limbs. The members of his Disabled Drivers' Motor Club are mostly deficient in one or two limbs. It is rather unlikely that the authorities will attempt to exact tests of physical fitness before issuing licences to drive, although one newspaper stated lately that tests for physical fitness would be instituted for applicants desiring to drive public vehicles. It is extremely doubtful whether in this or any other case the procedure will be of any real value. Blindness is probably the only defect which can be said certainly to be a bar to motor driving. Deafness need not incapacitate, since the deaf can train their eyes to greater perfection than the ordinary man attains. Defect in limbs, either from amputation or paralysis, does not necessarily disqualify, as Mr. Austin has shown. There remain for consideration certain diseases or conditions, such as heart disease, epilepsy, apoplexy, alcoholism, neurasthenia (which in police courts appears to have some affinity to alcohol), insanity, and old age. None of these conditions seems to be sufficiently amenable both to diagnosis and prognosis to make systematic examination of motor drivers justifiable. It may be agreed that a man with aortic disease or angina pectoris, an epileptic, an insane person, and perhaps a man who has had a stroke, ought not to drive motor cars. But the number of such persons who attempt to do so must be small, and the number of such

¹ Medical Research Council Special Report No. 6. Price 2s.
² Cmd. 2431. London: H.M. Stationery Office 1925. 3s. net.

persons who become involved in accidents still smaller. And though serious heart disease or the paralysis following a stroke are detectable, how is the epileptic or the madman who wishes to drive a car to be made to give himself up? As for the alcoholic, the neurasthenic, and the aged, few medical men would care to fix limits in these conditions within which driving might be considered safe. If a man of 80 is to be barred because of his age from jogging into the neighbouring village in his light car, why not make searching inquiries about the man who may have happened on some occasion to go to sleep at the wheel? It would probably be useful if the medical profession told the public authoritatively that in certain circumstances a man should refrain altogether from driving motor cars. Such circumstances might include liability to angina pectoris, to epilepsy, and a previous attack of apoplexy. With such information sufficiently disseminated, any sufficient from one of these conditions who caused an accident could be properly dealt with. As for the alcoholic and the neurasthenic, the medical profession may prefer to leave the fate of these persons to the wisdom of individual police-court magistrates. If a man cannot recognize that he is too drunk or too "nervy" to drive, he has himself to blame for his lack of judgement. The problem of disabled or defective motor drivers is interesting, and it is one in which the medical profession may be able to give guidance to the public.

BRIGHTON WORTHIES

BRIGHTON last week paid a tribute to some of the worthies of the past who have shown their appreciation of its health giving breezes by having their or giving it frequent visits. A tablet to the memory of Herbert Spencer, attached to a house in which he lived for some years, was unveiled by Sir John Ottewill. The second worthy to be honoured was Dr. Richard Russell, a memorial plaque to him has been put up on the site now occupied by the Royal Albion Hotel, on which in 1754 he built a house which became known as "Russell House".

Sir Frederick Mott, who unveiled this tablet, observed that, though Thackeray had said that the Prince Regent intended Brighton, it would be truer to assert that Dr. Russell discovered Brighton and made it famous. He wrote a dissertation on the use of sea water in the treatment of glandular disease, a copy of this book, written in Latin, was in the library of the Royal Society, and Dr. Russell might have got his idea from the line of Lauroides he quoted: "The sea washes away all the ills of man." In another book, which he gave to his friends, Dr. Russell had expressed his ideas of what a sea-bathing place should be and what Brighton was. "It should be clean and neat and some distance from the opening of a river, that the water may be rich with sea salt and the other riches of the sea. It should be bounded by lovely cliffs and downs to add to the cheerfulness of the place." Dr. Russell did not know at that time what science had now taught us to the value of sunshine for the cure of tuberculous diseases of the joints and glands. It was the invisible ultra violet rays of the sun that were helpful, and people when they basked in the sea got all the benefit of the sunshine and during their visit to Brighton spent much time in the open air. Pure sea air and sunshine helped Dr. Russell in the treatment of disease, made him successful, and Brighton fashionable. The third tablet, to Mrs. Fitzherbert, has been erected on Stone House, where she lived from 1804 till her death in 1837. It was unveiled by Alderman C. Thomas-Stanford. The fourth tablet has been placed on the Bedford Hotel, where Charles Dickens was a frequent guest. Afterwards a luncheon was given by the directors of the Bedford Hotel, the chair was taken by the chairman of the directors, and Dr. A. H. Copeman occupied the vice-chair. A toast was drunk to those who had unveiled the several tablets. Sir Frederick Mott, in his reply,

said that Dr. Russell must have been a very far-seeing man, and added that he had always looked upon Dickens as the greatest sanitary reformer the country had ever had. The menu was illustrated by a portrait of Dickens and by a facsimile letter written from Travestock House on November 30th, 1852, ordering a dinner at the hotel for himself and John Leech, which was to be ready for them at half-past four, when they would arrive after a walk on the Downs that morning.

IMMUNIZATION AGAINST DIPHTHERIA IN AUSTRIA

WE have previously (March 8th, 1924, p. 454, and December 6th, 1924, p. 1064) referred to the danger that may attend the use of toxin-antitoxin as a preventive of diphtheria, and further evidence of this is now supplied by Helmreich.¹ He reports that in a home for infants and young children at Baden, near Vienna, active immunization against diphtheria by toxin-antitoxin was carried out on forty children owing to an outbreak of the disease. Six of those inoculated died with local and general symptoms of diphtherial intoxication, and a number of other children showed skin necroses of various sizes at the site of injection. The 20 per cent. ovenacitized preparation of toxin-antitoxin which had been employed for immunization had been tested before use on guinea-pigs and found non-toxic. The fatalities could only be attributed to a dissociation of the toxin-antitoxin mixture, but the causes of this dissociation could not be determined. In the circumstances the Austrian Ministry of Health referred the matter to Professor Pirquet, who came to the conclusion that, in view of the mild form of diphtheria prevalent in Austria, active immunization was unnecessary, and that the following method, which had been employed in his clinic during the last few years, should be continued. Groups of children, including those in hospitals, infant homes, and schools, among whom there had been a case of diphtheria should be carefully examined clinically. Those with symptoms suggestive of diphtheria should at once be injected with antitoxin, while the Schick test should be performed on the others. Those with a negative reaction would require no further treatment, but those in whom the reaction was positive should receive a prophylactic injection of antitoxin. If the epidemic assumed a severe form, or if new facts were brought to light showing that an absolutely harmless vaccine could be prepared, the matter could be brought up for discussion again. In the meantime he recommended that active immunization should be discontinued. The Austrian Ministry of Health adopted Professor Pirquet's recommendation, so that active immunization of children against diphtheria has now been forbidden in Austria.

DE NOVO

ON October 9th (as recorded in our Scottish news this week) Professor John Fraser delivered at Edinburgh his inaugural lecture as Regius Professor of Clinical Surgery in the University, which he entitled "De novo." In it he imagined himself a student again, and outlined the education he would wish to be arranged for him as a future practitioner of medicine, in the light of his present experience. He viewed with regret the tendency of medicine to become every year more of a science and less of an art. Medicine is, perhaps, the most rapidly developing of all sciences, and in some respects is a mirror reflecting the progress of every branch of study, art, and profession. Fraser, the student pressing from his secondary school to the university, instead of appreciating the glorious freedom of the university method of education, finds himself in a close barred prison. The radical change in the method of instruction means a ship without a rudder. The cause of this defect, according to Professor Fraser, is to be found in

¹ *Elton Week*, August 27th 1925, p. 1697.

DR ANDREW BOORDE

the system of school education the student has never been taught how to work. The remedy suggested is that at a certain stage in his career, preferably before beginning the study of the basic sciences, every scholar should be given a short course in elementary logic, so that he may learn the logical process upon which the acquisition of knowledge is based. Then the science of induction—observation, elimination of the irrelevant, and inference—will no longer be a closed book. Beyond this Professor Fraser would have greater elasticity in the school curriculum, a reduction in the amount of set tasks and routine exercises, encouragement of nature classes, and simple studies in observation and deduction. The most productive course for later school years would be a liberal general education, including a sufficient knowledge of Latin and Greek to enable the student to understand the etymology of his profession, and as perfect a knowledge as possible of French and German, together with progressively intensified instruction in physics, chemistry, and biology. Were he once more at the stage of beginning *de novo*, Professor Fraser would be prepared to make great sacrifices to take an arts course before commencing the study of medicine. He is thus a strong advocate of general culture in the education of the future medical student. In his advocacy of a short course in logic he follows the late Mr C B Lockwood, who was in the habit of advising his dressers to read Jevons's little book on elementary logic. Though the volume was perhaps not very palatable, the advice was sound. Perhaps Professor Fraser, like Huxley, would prefer that the student should have obtained his acquaintance with logic by example rather than by precept.

DR ANDREW BOORDE 1490-1549

At the first meeting of the eighti-seventh session of the Liverpool Medical Institution, on October 15th, the President, Mr R C Dun, delivered an inaugural address on the life and writings of Andrew Boorde (1490-1549), his travels abroad, and his quaint observations set forth in his *Bolc of the Introduction of Knowledge*. Andrew Boorde, who latinized his name into Andreas Perforatus, was brought up as a Carthusian. He relinquished the order, and studied medicine at Orleans, Toulouse, Montpellier, secret Wittenberg. He was a friend of Thomas Cromwell, secretary to Cardinal Wolsey, and, it would appear, carried out confidential missions to France and Spain. In spite of his diatribe against the Scots—the devilish disposition of a Scotchman not to love or favour an Englishman—his wit is said to have been given birth to the word “merryandrew,” and the story of Tom Thumb has been attributed to his pen. His *Itinerary of Europe* has perished, it is said he lent it to Thomas Cromwell, who lost it. His *Itinerary of England* is still preserved, and gives a good account of England, its highways and castles, and contains quaint and at times scathing observations on Englishmen and their manners. There was, he said, in all the world no region nor country that doth use more swearing than is used in England. The *Bolc of Berdes* (beards) contains Boorde's denunciation of this male adornment interspersed in his prose are doggerel rhymes, of which Mr Dun gave an amusing sample. Boorde's purely medical works, the *Dietary* and the *Breviary of Health*, are full of sound common sense, more or less interwoven with alphabetical order and among articles of dress children's shoes are discussed. Idleness of youth is severely reprimanded, and overdrinking condemned at all periods of life, water, on the other hand, is strongly recommended. A house, Boorde insisted, should have a gravel foundation, pleasing views and plenty of air space if it had a moat the water should be supplied by a spring. Mirth and outdoor

exercise should be assiduously pursued, and dumb-bell exercise should be enjoyed when the weather is wet. On the other hand, he extolled shut windows at night, a scarlet nightcap, and a feather bed! Lastly, Boorde has given us the earliest known specimen of the gipsy language. He died in prison, probably for some political offence, and left his property to his fellow prisoners. Boorde was a versatile man, insatiable fond of travel, physician, humorist, a great believer in cultivating mirth, and honest in his piety. The members thoroughly appreciated the address and their thanks were proposed by Dr Abram and seconded by Dr Henry Harvey in graceful terms. Afterwards the President entertained the members to refreshments and music.

HEALTH WORK OF THE LEAGUE OF NATIONS

The Health Committee of the League of Nations met at Geneva for its fifth session on October 8th. Its business was to consider the several proposals made recently by the different Governments for the extension of its work, which had been referred to it by the Assembly. The Committee enumerated in our Geneva correspondent's article of September 26th (p 578) One matter of particular interest to the British Empire is a request from the High Commissioner for the Union of South Africa that the Health Committee should undertake an investigation into the prevalence of tuberculosis amongst native tribes in South Africa, and especially amongst the natives employed in the mines. The League Council has approved the recommendations of the International Conference on Sleeping Sickness, held in London last May, and arrangements have now been made for the dispatch of the international commission of investigation which is to spend next year at Entebbe, Uganda, studying this disease with the aid of the Government laboratories placed at its disposal by the British authorities. It was also decided that medical officers from Great Britain and eight other countries are to make a collective study of health organizations in all the principal Mediterranean ports, and another interchange in which medical officers from Australia and New Zealand and a number of Asiatic countries are participating is being held this month in Japan.

ELIZABETHAN MEDICINE

As announced, the first social evening of the Royal Society of Medicine this session will be held on Tuesday next, October 27th, at 8.30 p.m. The President, Sir St Clair Thomson, after receiving the guests, will give a short address on “Shakespeare as a guide in the art and practice of medicine.” The exhibition arranged by Mr C J S Thompson of the Wellcome Historical Medical Museum will embrace portraits of the leading physicians of the Elizabethan period, as well as books, engravings, medals, and specimens (with appropriate quotations) of all the drugs and medicinal plants mentioned in the plays. It has been arranged for the exhibits to be on view at 2 p.m. on Tuesday, and to remain available until Wednesday at 5 p.m.

The autumn lectures at the Royal College of Physicians of London will be given as follows: the Bradshaw Lecture by Dr Edwin Bramwell, on the myopathies, on Thursday, November 5th, the FitzPatrick Lectures by Dr Arthur Shadwell, on medicine in ancient Egypt, Assyria, and Palestine, on Tuesday, November 10th and Thursday, November 12th. These lectures will be given at the College at 5 p.m. As already announced, the Lord Roberts Lecture by Sir Arthur Keith, on man's structural defects, will be delivered at the house of the Royal Society of Medicine (1 Wimpole Street W.) at 5.30 p.m. on Monday, November 16th.

Nova et Vetera.

VISUAL HALLUCINATIONS

MR ARTHUR OMOND has raised a very interesting question in the paper which he read before the Section of Ophthalmology at Bath on "Visual hallucinations in sane people" (*BRITISH MEDICAL JOURNAL*, August 29th, 1925, p 376). Some of those which he described were doubtless, as he suggests, manifestations of migraine of an unusual type, others, again, seem to be merely visual memories of things seen, of which the mental memories have faded away. Mr Omond remarks that this subject seems to have attracted more attention at the beginning of the last than in the present century. This is doubtless true, and so much has interest in the subject declined that even Mr Omond makes no allusion to the remarkable facts recorded by Sir David Brewster, and published in his *Letters on Natural Magic*, addressed to Sir Walter Scott, whose interest in tales of demonology and witchcraft was well known. The celebrated case of "Miss A," which was recorded in that book, presented some remarkable features, in that the hallucinations were not only visual but also auditory, and that some of the former could not be memories of things actually seen and forgotten, seeing that they represented appearances which could not have at any time been presented to her external visual organs.

Some of the illusions of sight and sound to which Mrs. A. was subject were such as are familiar to readers of well authenticated and of fictitious ghost stories. The well known voice which called to her as if for help, the appearances of her (living) husband and of deceased friends, and particularly the form of an absent friend, which, clad in grave-clothes, was seen in a mirror, were, however, unconnected with any tragic circumstances at the time or afterwards. The husband whose plaintive voice appeared again and again to her to come to him was at the time in no difficulty or distress, and was then and long after in good health. Those who think that appearances of deceased persons are supernatural will consider that Miss A.'s experiences in this connection were of grave psychical importance. Miss A. herself did not attach any such meaning to them. The lady who appeared in such gruesome garments in the mirror while Miss A. was dressing her hair was at the time alive and well, and neither she nor Miss A. was one penny the worse for the experience. One rather persistent apparition of a deceased friend, which seemed to be seated in a chair and showed no disposition to fade away, was got rid of by Miss A. sitting down in the chair herself and feeling no resistance in so doing. She owed the hint on which she thus relied to Sir Walter's book on demonology.

Although the mind of Miss A. was in no way deranged she was in a weak state of health at the time when she was subject to these illusions, and there can be little doubt that this circumstance was closely connected with the appearances. Dr Samuel Hibbert,² who wrote on apparitions a hundred years ago, laid much stress on the influence of bodily health in the production of spectres and hallucinations and brought forward much evidence in the support of his theories. At that time the inhalation of nitrous oxide gas was a novelty, and it is interesting to note the very extraordinary effects on the mind which its inhalation seems to have produced. It is, of course, to be remembered that a rather free dilution with air accounted for the excitement caused by "laughing gas." But just as the first experimenters with the electric shock from a Leyden jar declared that they felt results far beyond the every day experiences of modern schoolboys, so the new gas in the glow of its recent discovery caused visions and dreams of surpassing beauty or wellnigh unspeakable horror.

Dr Hibbert described appearances which, like those seen by Mrs. A., ought, according to all orthodox ghostlore, to have been followed by disaster, but which, like hers, had no notable sequel. Seers have been men and women of

various grades of intellect. A coler, the Berlin bookseller, who was so persistently "haunted," was a very intelligent man. Martin Luther is certainly no fool, but he had many dealings with the visible and the invisible, who, among other announcements, disturbed the reformer by creaking nuts against his bedpost.

"Dr Johnson said that one day at Oxford as he was turning the key of his chamber he heard his mother distinctly calling, 'Sam.' She was then at Lichfield, but nothing ensued."

The believers in the prophetic or spiritual significance of wraiths may retort on such instances that there is a vast majority of recorded cases which are connected with death or disaster, and the sceptic may answer that very few of the cases without sequel are recorded. How much the mental attitude of cultivated persons has changed may be judged from Dr Hibbert's notes on Dr Johnson's experience, that—

"This casual admission which in the course of conversation, transpired from a man, himself strongly tainted with superstition, precludes many further remarks on the prophetic nature of these impressions, which would now indeed be highly superfluous."

Dr Hibbert could hardly be expected to foresee Sir Oliver Lodge and Sir Arthur Conan Doyle and all the twentieth century seers of furies and heretics of spooks, any more than he could foretell such scientific developments as wireless telegraphy and the internal combustion engine. For our part, we confess to a preference for the merry if mischievous devils of Martin Luther and Reginald Scot, whose *Discoverie of Witchcraft and Discourse on Devils and Spirits* will repay its reader, as much for its racy English as for its unintentional as well as its intentional humour.

HEALTH ORGANIZATION IN SOUTH-EASTERN EUROPE

THE Health Section of the League of Nations has added two new monographs to its series descriptive of the organization of public health services in the countries belonging to the League. One is for Czecho-Slovakia and the other for Serbia and its new provinces.

Czecho-Slovakia

Czecho-Slovakia is a republic under an elected president, and was carved out of the Austro-Hungarian Empire. Three of its provinces (Bohemia, Moravia, and Silesia) were formerly under the crown of Bohemia, and two (Slovakia and Ruthenia) belonged to Hungary. Each province had its own administrative government and when the State of Czecho-Slovakia came into existence each province retained its own administrative powers, inherited from the old system. From the outset endeavours were made to establish uniformity, but nevertheless Dr Hynek J. Pele, D.P.H., whose essay on the organization of the public health services in Czecho-Slovakia is now two years old, had an extremely difficult task. Czecho-Slovakia has an area of fully 54,000 square miles and a population of more than 13½ million. The plan formed was to divide the country into counties and county districts, with district committees and district offices, and county councils and county committees, charged with financial, sanitary, and social responsibilities, with roads, and with educational establishments. An exception was made for Ruthenia, which, with its local Diet, remained independent, though attached to the republic. For want of funds, however, the plan has not so far been carried out, excepting in Slovakia, and though it is being considered for Moravia years will probably elapse before it is generally adopted throughout the country.

It is not our purpose to follow Dr Pele through his interesting and detailed account of all that is being done for public health in Czecho-Slovakia. With the aid of the Rockefeller Foundation and State Institute of Hygiene is being established, it will consist of several sections devoted to the Pasteur treatment, the production of small-pox vaccine, the analysis of foodstuffs and drugs, experimentation in water purification and sewage disposal, and so forth. Attached to it will be a school for training medical officers of health. Other subjects dealt with by Dr Pele are the

etc. By Samuel Hibbert Edinburgh, 1823.)

England and Wales.

Sir WILLIAM HAMER's Successors
 On October 20th the London County Council appointed Dr F N Kny Menzies to be county medical officer of health and school medical officer in succession to Sir William Hamer, whose forthcoming retirement was announced in our last issue. The Council, in July last, decided to invite from its medical staff, permanent or temporary, whole time or part-time, applications for the appointment which was to become vacant at the end of the year. Nine applications were received, and a special sub-committee was set up to interview all the candidates and to advise as to the appointment. As a result of this preliminary sifting out, two candidates appeared before the General Purposes Committee, and after interviewing them the committee unanimously decided to recommend to the Council the appointment of Dr Menzies. The appointment will date from January 1st, 1926, and the salary will be £2,000 a year. Dr Kny Menzies graduated in medicine at the University of Edinburgh in 1899 and proceeded M.D. (with distinction) in 1903. He obtained the D.P.H. of the London Conjoint Board in 1905, and was elected I.R.C.P.E.d in the following year. After graduation he studied abroad for a year, and held resident hospital posts in London, Edinburgh, and Dublin. From 1907 to 1911 he was lecturer and demonstrator in the public health laboratory of University College, London, and deputy medical officer of health for Stoke Newington. He then became a whole-time assistant medical officer under the London County Council, and in 1914 was appointed principal assistant medical officer in the public health department. In this capacity he was responsible for the organization which built up the London County Council schemes for the diagnosis and treatment of tuberculous and venereal diseases. In April, 1924, the Council appointed him consulting medical officer for these diseases, on his election as director of the hospital and medical services department of the Joint Council of the Order of St John and the British Red Cross Society. Dr Menzies' other recent activities have included membership of the Voluntary Hospitals Commission and of the Trevelyan Committee of inquiry into the means of preventing venereal diseases, and he has represented Great Britain at international medical conferences held in Cannes, Geneva, and Copenhagen. His latest annual report on the voluntary hospitals of Great Britain was summarized in our last issue (p. 717).

called for, but without a specialist medical practitioner is not able to obtain medical aid at all."

Malaria—A very important section of Dr Stampar's report is devoted to malaria. The kingdom "is one of the most malaria-infected countries in Europe. At the present moment more than a million of its inhabitants are suffering from this disease, it is impossible, on account of the lack of doctors in certain parts of the country and of transport difficulties, to ascertain the exact figures, but we know that the whole of Dalmatia, the islands off the south coast, the southern part of the former Montenegro-Herzegovina, the southern reaches of the rivers Save, Theiss, and Danube, and the whole of Macedonia, are infected. The great number of cases and the material loss entailed thereby have made malaria one of the most anxious problems with which the kingdom has to cope." In 1921, in certain districts in Dalmatia with 32 548 inhabitants, 10,315 were examined, and it was found that 7,503 of them were suffering from malaria and that 73 per cent had enlargement of the spleen. Following these impressive statements an interesting account is given of research during, and since the war. It is clear, however, that control of malaria is the most tremendous problem with which the new kingdom has to deal. Indeed it may be said that its whole prosperity, even its national survival, depends on the success of its antimalarial policy and work. Malaria in South-Eastern Europe was further referred to in our article on the epidemiology of 1924, published on September 12th (p. 483).

WORKSHOPS FOR TUBERCULOUS PERSONS

In connexion with "Health Week" in the Borough of Holborn, a conference was held at the town hall on October 7th for a discussion on the provision of workshops suitable for tuberculous men and women. The Mayor of Holborn (Mr H Warren Coleman, J P) said that in the borough at Hatton Garden, such a workshop for men had been in existence for some time, and had proved in many respects successful. He hoped that, following upon the suggestions made at the conference, it might be possible to start a workshop on a larger scale, and one which would employ women as well as men. Mr G H Walmisley (chairman of the Public Health Committee of the London County Council) described some of the difficulties which faced any local authority in tackling tuberculosis. One great source of difficulty was that the benefit received by the tuberculous person under national health insurance was provided for only a limited time, and for this reason the persons often discharged themselves from sanatoriums earlier than the authorities considered desirable. The London County Council had suggested to the Royal Commission on National Health Insurance that surplus insurance funds should be devoted in part to subsidizing work shops in such a way that a living wage could be afforded for those who were unable to do a full day's work. The alternative was, indeed, which was had economically and from the point of view of the patient's own chances of recovery. Dr Otto May (read at

office to the Prudential Assurance Company) said that insurance companies realized very clearly the importance of this subject in view of the heavy claims which tuberculosis made upon them. But it was obvious that such workshops could not be self-supporting. The large insurance companies had considerable reserves, and although this money was not for the purpose of experiment he thought that assistance might be forthcoming from other quarters. Dr. Irden Guest, M.P., wished to see the establishment of workshops where persons could work while still under medical treatment. At present some medical men failed to notify tuberculosis from their desire not to deprive a man of his work. One method of dealing with the matter would be to pay, through national health insurance, a special sickness rate for tuberculosis in its early stages. He agreed that value and he was glad to hear the doctrine enumerated that a subsidy in this particular respect was really excellent. He suggested that the organizers of the Holborn workshop should get into touch with local trade unions and ask their co-operation in propagandists among their own members, both with regard to the need for early notification and the detrimental nature of the disease to society as a whole. Dr. Harry Campbell spoke of the number of tuberculous patients who were capable of performing light work and yet looked about, leading aimless lives. It would be of great advantage if they could be collected together and given work in workshops constituted under the most hygienic conditions, and workshops of this kind would be a boon both to the patients and to the community. Dr. Noel Birdswell, representing the Central Fund for the Industrial Welfare of Tuberculous Persons, said that the Hutton Garden factory was the first of its kind in London, and complemented the factory was twenty-four persons, at present twenty three were employed there the youngest, at 16 years of age. They worked from 8.30 a.m. to 5.30 p.m., with certain intermissions, and every year had a holiday on full pay. Medically speaking there was no question that these workshops had been an enormous success. There had been quite a small amount of sickness, and a surprising improvement in general health. Dr. Lennane (M.O.H. Battersea) also welcomed the experiment, and mentioned that his own borough was a pioneer in dispensary treatment. Various suggestions were made for the more suitable and extensive employment of tuberculous persons. It was urged that the problem was a national and not a local one and called for the formulation of some national scheme. One speaker suggested that attention should be turned to forestry as a suitable employment for tuberculous persons, especially in view of the report of the Commission on Forestry that there were 21 million acres of ground available for this purpose.

THE ANNUAL MEDICAL SERVICE IN LIVERPOOL

The annual medical service in Liverpool was held on St. Luke's day (Sunday, October 18th) at the Cathedral. There was a large attendance of medical men and women, of whom some wore academic dress. The Lord Mayor, Raven D.D., and the Cathedral was full. Canon for his text preached the sermon, taking Acts vii, 9, 10, and it was only through the combined efforts of medicine and religion that permanent improvement could be secured. He looked forward to the future with hope, realizing how important this was in medical practice. There was in the priest and physician much in common, and God's gifts well known of mankind. The Bishop of the diocese gave the benediction. The musical part of the service was beautifully rendered and the anthem "Ho, every one that fully rendered and the anthem "Ho, every one that thou. Mr. H. Gosse Custard, Mus. Bac. Oxon, the

Cathedral organist, was at the organ. The offertory, on behalf of the Royal Medical Benevolent Fund, amounted to £111. Dr. J. Ernest Nevins, 32, Princes Avenue, is the local honorary treasurer, and he will be pleased to receive donations from those who were unable to be present. The arrangements and marshalling of the medical men and women in the stately procession from the chapter house along the ambulatory to their places were carried out most efficiently. A word of thanks should be given to Dr. Nevins for his untiring efforts, which made this service a memorable occasion in the medical life of the city.

TREATMENT OF MENTAL DEFECTIVES IN SOMERSET

On September 23rd a residential special school and home for mentally defective girls in Somerset was opened at Sandhill Park, Bishop's Lydeard, by Dame Monica Wills, the widow of the late Mr. Henry H. Wills, who had been a very prominent supporter of this scheme. About forty patients are at present residing on the premises, which will accommodate 119. The estate will be developed later into a farm and industrial colony for the feeble-minded. The necessary alterations of the house were planned by Sir George Ortleigh, who designed the buildings of Bristol University. Mr. J. Cooke Huile, chairman of the Somerset County Council, referred to the opening during last summer of a county hospital for consumptives, and emphasized the value of the work of the Somerset branch of the Voluntary Association for the Care of the Feeble-minded. After paying for the equipping of the building presented to them by Mr. H. H. Wills, there still remained more than £10,000 for the cost of further extensions. The chairman added that about 1,000 mentally defective patients in the county, who did not require institutional treatment, were being kept under supervision by voluntary helpers, in this way considerable expenditure was being obviated.

PREVENTION OF DIPHTHERIA AMONG LONDON SCHOOL CHILDREN

Following upon a resolution of the London County Council last year, referring it to the Public Health and Education Committees to consider and report whether or not the treatment carried out by the department of health in New York City for rendering children immune from diphtheria should be adopted in London schools, the two committees reported to the Council on October 13th that they had had before them a review by the medical officer of the work which had been carried out in connexion with diphtheria immunization for the control of diphtheria, both at home and abroad, and that it was understood that the Ministry of Health was conducting inquiries with regard to immunization of the staffs of fever hospitals and in connexion with maternity and child welfare work. The committees had been advised that these lines of investigation should be thoroughly explored before further consideration was given to the question of immunization of children of school age, and therefore they were of opinion that it was not advisable at the present time that toxin antitoxin treatment in connexion with the prevention of diphtheria should be adopted as part of the Council's scheme of medical treatment of school children.

LEICESTER PERSONAL HEALTH ASSOCIATION

The Leicester Personal Health Association has recently been inaugurated with a view to developing further health propaganda in the city of Leicester and to act as a medium for disseminating sound information on public health and general health, in order to educate the public in preventive measures. It is proposed to hold short lectures fortnightly from October to April of each year, at which medical authorities and others will speak on health subjects. The objects of the association have been approved by the Leicester and Rutland Division of the British Medical Association. The president is Dr. R. Wallace Henry, and among the vice-presidents are Mr. C. J. Bond, I.R.C.S., Dr. C. Killick Millard, the local members of Parliament, and other prominent citizens of Leicester.

SCOTLAND

CHAIR OF CLINICAL SURGERY AT EDINBURGH
PROFESSOR JOHN L. FRISER, M.D., Ch.M., who was appointed last summer to be professor of clinical surgery in the University of Edinburgh in succession to Sir Hugh Stiles, delivered his inaugural address under the title "De novo" on October 9th.

After references to some of his predecessors in the chair, Professor Friser discussed some points in the medical education of students. Medicine, he said, must be regarded as a science which was concerned with the balancing, scrutiny, and investigation of facts the result being achieved by the employment of mechanical devices, combined with the aid of mechanical devices. He believed it to be true, although he acknowledged it with regret, that with every very medicine became more of a science and less of an art. In some respects it was the mirror in which was reflected the progress of practically every study pursued by the physicist, the chemist, the artist, and the inquirer. Medicine adopted and adapted all these, for its aims were very ethereal and its interests very wide. The student who passed from a secondary school into a university had a terrible first experience. He appeared to have attained a glorious freedom, and yet the lecturer who had been rather like a prison with the closest bars, because others had found the change in the method of instruction so far as he had never been taught at school how to work. The science of induction—observation, elimination of the irrelevant, and inference—was a closed book to him. Between man and man there was concerned, it was the case where mental machinery was concerned, and many a student came to the university with a vital deficiency which he had never been taught at school how to work. The science of induction—observation, elimination of the irrelevant, and inference—was a closed book to him. Between man and man there was concerned, it was the case where mental machinery was concerned, and many a student came to the university with a vital deficiency which he had never been taught at school how to work. The science of induction—observation, elimination of the irrelevant, and inference—was a closed book to him. Between man and man there was concerned, it was the case where mental machinery was concerned, and many a student came to the university with a vital deficiency which he had never been taught at school how to work.

THE SHOULDER BLADE AS AN INDEX TO HUMAN TYPES

Professor William W. Graves, M.D., Professor and Director of the Department of Medicine, St. Louis University, U.S.A., delivered a lecture on October 16th in the anatomy classroom of Edinburgh University, dealing with the "Relation of shoulder-blade types to problems of mental and physical adaptability." The lecture was given under the auspices of the Henderson Trust, and Lord Salvesen occupied the chair. The lecturer recalled that no structures in the organism of man had been more carefully studied than his bones, which expressed his individuality, and determined other bodily form. Notwithstanding the processes of growth, they largely preserved their individual characters from birth to the grave. In 1806, Professor Graves continued, he became impressed with the fact that shoulder-blade differed in type, though no one previously had noted any particular differences in them. Most textbooks of anatomy described the vertebral border of the shoulder blade as convex, but shoulder-blades could be classified into convex, straight, and concave types, and he found that this classification ran through all accepted racial and modern human stocks, and also through the human species. By the tenth week of foetal life the shoulder blade had attained the essential form to which it ever afterwards conformed. The type of shoulder blade was handed down from parent to progeny. In America 80 per cent of the population presented straight or concave types in the first ten years of life, whereas in the age period between 70 and 80 years only 20 per cent possessed these types. The three possible explanations. Either that one type changed into another by the natural process of senescence, or that environmental influences, such as occupation, disease, etc., changed one type into another, or that on type of scapula was found in potentially longer-lived individuals. There could be no biological reason why human beings should have the same type of shoulder blade any more than why they should all have the same type of skull or other morphological feature, but he would hesitate to say that environmental influences could give one chimpanzee a convex, another a straight, and another a concave type of scapula. The fact that scapular type were usually constant in transmission from one generation to another, and that the type was marked in early life, remained more or less fixed after their earliest formation. The inference was that mortality was greater among the possessors of the straight and concave, especially the concave, than among the possessors of the convex scapula. He believed, therefore, that the application of scapular classification would lead to the recognition of factors underlying individual health and disease.

ROYAL MEDICAL SOCIETY OF EDINBURGH

The 189th session of the Royal Medical Society of Edinburgh was opened in the Society's Hall on October 16th with an address by Sir James Purves Stewart, K.C.M.G., M.D. The chair was occupied by the senior president of the society, Dr. Drummond Shiels, M.P., who said that the Royal Medical Society was the oldest society of its kind in the world. It occupied a unique position in the affection of its members and in the enthusiasm with which its active student members took part in its weekly meetings. Sir James Purves Stewart entitled his address "Comradeship in science." He said that the biological importance of the herd instinct could hardly be overestimated, and independent individuals became more efficient when combined into families, nations, and races. The lowest type of herd, said the lecturer, giving examples from the animal kingdom was that of the communists, where all were equal workers and fighters. There were also types where one individual was entrusted with a kind of monarchy as in the case of the queen bee. Similarly, man could only

reach his highest development by following this instinct, and in civilized communities the herd instinct was the dominating instinct, and had imposed restraining influences upon the other instincts. Socialism of a constructive type, he said, had prevailed in a small but important part of the community, and men of science had formed a habit of pooling their knowledge for the general advancement of science. Advances in science were rendered more possible by team work. Men of science did more than share their knowledge with one another, for they let the whole world profit in their discoveries. As an example, he pointed out that the working man rode every day for 2d in an electric tram although he might know nothing of electricity. He reached his destination, was taken to the surface by a moving staircase, of the mechanism of which he was ignorant, if he stepped off with the wrong foot first and was hurt, he was taken to hospital, where medical science, of which again he knew nothing, did all that science could do for him, and did it for nothing. (Laughter.) That was the socialism of science, and what did it receive from those who profited by it? They all knew the answer. The hospitals were chronically in debt, and research was half stunted, for practically no return was made by the great body of laymen in any way commensurate with the advantages they so eagerly accepted.

DR. COMRIE'S ADDRESS ON OLD TENDENCIES IN MEDICINE

At the opening of St. Mungo's College, Glasgow, for the session 1925-26, on October 13th, Dr. John D. Comrie, lecturer on the history of medicine and on clinical medicine in the University of Edinburgh, delivered an inaugural address dealing with "Some Old Tendencies in Medicine." The lecturer said that it was interesting on an occasion such as the opening of a medical school to refer to what had been said in an address by Erasmus about the year 1500 to the students of Louvain University. He had stressed the usefulness of the physicians in his day, referred to the high esteem in which they were held, and pleaded that those who practised medicine should be adequately paid. He had also usefully declared that "In our days mortals think that it is not their business if poisons are sold for wine, or if diseased corn or rotten fish spreads disease among the people." At the beginning of the sixteenth century there had been no Public Health Department and very little sanitary law, which was the main reason for the devastating character of epidemics in the Middle Ages compared with their limitation at the present time. A great tendency in every generation was to regard its own medical knowledge as supreme, it not final, and this attitude had been expressed with naive complacency by Ambroise Paré in the conclusion of his book on surgery, which had been a great and novel work at the time of its publication in 1579. Paré concluded "I have so certainly touched the mark at which I aimed that antiquity may seem to have nothing wherein it may exceed us, beside the glory of invention, nor posterity anything left but a certain small hope to add some things, since it is easy to add to former inventions." This was a remarkable statement in view of the experience which they now had of the great additions to surgery since his time. Continuing, Dr. Comrie said that they possessed a very complete picture of medical theory and practice as it existed at the time when Greek intellectual activity reached its zenith, about four centuries before the Christian era. Some alteration of the "humours" or body fluids was held responsible for the changes that produced disease. The humours were supposed to be four in number—blood, phlegm, yellow bile and a hypothetical humour, black bile. Harvey's great discovery regarding the circulation of the blood in the seventeenth century had drawn away men's thoughts from the humours. It had stimulated Boyle, Hook and others to investigate the manner of respiration, and they had shown that air was necessary for life as well as for combustion. An unfortunate theory, which had slain its tens of thousands, had developed upon this discovery in the phlogiston theory advanced by Stahl at the end of the seventeenth century. He had supposed that when a substance wasted away in burning it gave off an imaginary substance, phlogiston. This supposition led him to suggest

that in fever it was a good plan to get rid of phlogiston quickly by bleeding the patient. Hence the antiphlogistic process of blood-letting, which had had a moderate vogue in ancient and mediæval times, increased in the eighteenth century to alarming dimensions, and continued to into medical practice until well on into the last century. The middle of the nineteenth century was a most important time in medicine: the use of anaesthetics became general, antiseptic surgery was introduced, a new conception was given to biology by the publication of Darwin's *Origin of Species*, and Virchow showed the importance of the cells in the body, which he regarded as "a cell state in which every cell is a citizen." The omnipotence of the cell dominated medical thought during the latter part of the nineteenth century, but in the twentieth century a revision to the importance of the body fluids (humours) took place, and many diseases were now known to be due to diminution or excess of secretions prepared by various glands, so that the humours were found again to be of importance undiminished even by the ancient physicians.

Dr. Comrie said that another broad avenue with numerous by paths, through which, during the ages, the healing art had been excited, was the influence of mind. In ancient Greece the priests of Asklepios had been regarded by the public as of equal importance with the practitioners trained in medicine, and with the philosophers who investigated scientific problems. People betook themselves in great numbers to the shrines of Asklepios for treatment by suggestion and charms. The practice had been humorously satirized by the dramatist Aristophanes in the comedy of *Pluto*, in which the god of wealth was supposed to betake himself to one of these shrines as a patient to be cured of blindness. In the Middle Ages this method of healing had been assumed in prayer and invocation by the Church, and among the ultra-spiritual, like St. Gregory of Tours, it had been accounted as sin to have recourse to earthly means of treatment even for so obviously physical a disorder as tooth-ache. The element of mystery played an important part in all these systems of faith healing. One of the most surprising developments in this line of treatment had been the modern success of Christian Science, which, beginning in 1866, now numbered the adherents of some 700 congregations in America and Britain.

So far, the lecturer said, he had considered the tendency to look for the origin of disease within the body or mind, but mankind, from the earliest stages, thought diseases also came from outside. The primitive man had believed that demons and spirits beset him from the desert or the woods. In the Middle Ages the heavenly bodies had been supposed to exert a great influence upon health, the macrocosm of the universe having an occult influence on the microcosm of the individual. A most useful discovery was made by Leeuwenhoek during the seventeenth century soon after the invention of the microscope, in those minute forms of plant life which we called bacteria. Methods of studying these, which originated from the genius of Pasteur and Koch some fifty years ago, had led to the identification of about forty bacteria as causes of definite diseases, and had founded the great science of bacteriology. Continuing, Dr. Comrie said that, although the tendencies in medicine of the past still lived at the present day, new problems constantly arose as diseases changed in relative importance. In the immediate future the tendency would be to combat those diseases which were of social importance. Legislation would attempt to supply purer food, obtain healthier dwellings, and restrict communicable diseases. The old principle of charitable hospitals established by wealthy members of the community for the poorer classes, which had originated with the Arabs and had been introduced into Europe by Louis IX and Pope Innocent III in the thirteenth century, was being displaced by the conviction that provision of hospital services was a matter for insurance just as much as provision against loss by fire. The encouraging fact had been pointed out by Sir George Newman that every child now born in Great Britain had an expectation of life approximately twelve years longer than that of its grandfather, although it was obvious that much remained to be done, since 40 per cent. of all deaths still took place under 50 years of age. In 1924 the sickness among insured persons had entailed more than 23 million weeks of lost work, or the equivalent of 447,000 persons off

IRELAND

work for the whole year, and this meant a great loss of wealth and happiness to the general community. The great tendency of the immediate future would be for the collected forces of preventive medicine to attack these problems. This would lie mainly with the general practitioners of the country, and the chief aim of medical schools should be to turn out good general practitioners. The tendency in some countries to seek the easy path of specialism and avoid the labour of general practice was reminiscent of the old Greek proverb, "There are too many drivers of oxen, and too few tillers of the soil."

ANDERSON COLLEGE OF MEDICINE

The formal opening of the Anderson College of Medicine, Glasgow, for the winter session took place on October 13th, when an address was delivered to the students by Mr Alexander Miles, F.R.C.S., LL.D., of Edinburgh. Mr J. B. Kidston, president of the governors, occupied the chair. Mr Miles took as his subject "The co-ordination of medical study," and pointed out that the medical curriculum was so framed as to turn out a well equipped and properly instructed family practitioner. The young student should at the beginning of his course try to each that his studies bore some logical relationship to each other. Professional study fell into four groups. In the first of these the student, in the subjects of chemistry, physics, and biology, learned the importance and far-reaching effects of great natural laws, and was so trained in observation and experiment as to be able to prove the truth of these laws for himself to a certain definite extent. In this way the scientific frame of mind was developed. Then followed the second group, embracing anatomy and physiology, or the study of physiology and anatomy gone wrong so to speak, and pharmacology, or a consideration of the means by which disordered action might be put right again. The student was thus made fit to deal with the living human being in sickness, and so proceeded to medicine, surgery, and the special groups, and if he had co-ordinated his studies might be able to attack the problem of the sick person in a scientific fashion resting on great broad principles. Lastly, in the subjects of forensic medicine and public health he learned of the application of medical science to the community as a whole, in the one case in the interests of medicine and the other in the direction of preventive medicine. The address was provision of a healthy environment. The address was listened to with great attention by a large audience of students and staff, and at the close a hearty vote of thanks was recorded to Mr Miles on the motion of the Dean, Professor Christies Douglas.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH,
ST ANDREW'S

On October 13th Dr Douglas Guthrie (Edinburgh) introduced a discussion on prognosis in middle-ear suppuration. Though this was known to be a common condition, Dr Guthrie expressed the belief that it was often overlooked. Pus did not flow from the ear in all cases, and might be small in quantity, the common type of deafness, oto-sclerosis, was held by some authorities to be the result of previous inflammation in the middle ear which had escaped notice. Dr Guthrie was convinced that a proportion of deaths attributed to "meningitis," etc., over their persistent middle-ear disease, and that in many cases persistent otitis media resulted in chronic ill health, while secondary pulmonary, and digestive diseases were common. He alluded to the unsatisfactory terminology in use in regard to otitis media, commenting on the vagueness of meaning of such terms as acute and chronic and catarrhal otitis media, all of which merely represented degrees of the same process. He directed the notice to several anatomical features which affected the nature and progress of the condition—for example, the short, wide, straight Eustachian tube of infants, etc. In this connection he emphasized the danger of unexplained otitis in children and referred to cases of unexplained otitis in children

in which, in spite of a normal appearance of the drum, pus was proved to be present on paracentesis (so called latent otitis media). The bulk of his paper dealt with the results of an investigation of the subsequent history of 345 cases of otorrhoea over a period of years, which was undertaken at the instigation of Sir James Mackenzie, it had proved most illuminating. The ultimate results of various operative procedures as regards life and deafness were illustrated, and is a result of comparison of these it became clear that the more radical forms of surgical procedure should be discarded. It was also evident that deafness was more commonly the result of previous middle-ear inflammation than was supposed. A discussion followed and Dr Guthrie was warmly congratulated on his account of his investigation.

Ireland.

BELFAST MEDICAL SCHOOL OPENING OF THE
WINTER SESSION

The opening address of the winter session of the Belfast medical school was delivered by Professor C. G. Lowry, in the King Edward VII Memorial Hall of the Royal Victoria Hospital, on October 15th, Mr A. B. Mitchell, chairman of the medical staff, presiding. Professor Lowry, welcoming the students, recalled his own entrance to the school twenty-six years previously, when he had listened to the inaugural address of Mr Karl, in the old Royal Hospital in Frederick Street. At that time they had one operating theatre, an inadequate outpatient department, no laboratories and only 200 beds in a dingy building nearly a hundred years old. At the present time they had 400 beds, eight theatres, magnificent laboratories, a modern x-ray department, and a dental department. The membership of the staff had increased from fifteen to thirty-five, and the deepest gratitude was felt to all who had co-operated in this work of extension, particularly to the late Viscount Pirrie and to his widow, Lady Pirrie, their president. The importance of the clinical education of the medical students, especially in not-taking, could not be overestimated. Hospital work was the best training for the general practitioner, the specialist, the hygienic and tropical medicine. The medical student must not attempt to do in the services, as also for practice in hygiene and tropical medicine. The amount of work that was intended to occupy a session. He was at first liable to get behindhand in his work and to be discouraged by its magnitude. The second hindrance was the habit of procrastination, and the third the familiar practice of sitting up late at night over work, with the almost inevitable sequel of late rising in the morning. In their dealings with patients they should always remember that they were the trustees of the good name of the hospital. Professor Lowry then advised the students to make a habit of reading up each evening one case examined that day in the wards, it was surprising how knowledge grew from such a regular performance. Medical biography was both a relaxation and a help, in the first place came the biographies of Pasteur and Jamieson, which every medical student should read, since they gave a medical and scientific history of the greatest period of progress in the history of mankind. In spite of the great advances that had been made, much remained to be done, and the present students might look forward to seeing the conquest of malignant disease, the eradication of the problems of maternal mortality in childbirth, the reduction of maternal mortality in childbearing.

Professor J. A. Lindsay, chairman of the board of management, proposing a hearty vote of thanks to the lecturer referred to the valuable advice and pleasant glimpses of humour that had been forthcoming. He also mentioned the enlargement and improvements of the hospital. The vote of thanks to Professor Lowry was seconded by Sir Robert Band, D.L., supported by Professor Thomas Sinclair M.P., and passed with acclamation.

HEALTH OF BELFAST

The annual reports of the medical officer of health and of the chief tuberculosis officer for 1924 have lately been presented to the respective committees. The estimated population of the city is 434,000, an increase of 5,000 over last year, the birth rate is 23.9 per 1,000 of the population, a decrease of 1.1, and the death rate 14.3 per 1,000, this is an increase of 0.5, but is 2.8 below the average of the last decennium. The estimated figures at the end of a census period are always unreliable, and, as it is fifteen years since a census was held, those now in use are probably more unreliable than usual. Every factor, however, points to a greatly increased population, to a falling birth rate, and to a greatly improved death rate. This satisfies the man in the street. Of the total deaths registered 1,948, or 30.78 per cent, were due to chest affections. The number of deaths due to phthisis was 605. Deaths due to zymotic disease numbered 421, only 3 were from typhoid, a disease formerly rampant in Belfast. The number of deaths attributed to cancer was 424. There was an increase of 943 in the total number of notifications of infectious disease, of which 1,818 were due to scarlatina, and 221 to encephalitis lethargica, a considerable increase over the figures of 1923. It would be instructive to have a review of the scarlatina epidemics since the opening of the city infectious hospital, the large number of cases of epidemic encephalitis, with all its distressing sequelae, also demands full investigation. A special report from Dr Gaidner Robb, the medical officer of the hospital, with his long experience and intimate knowledge of the town, would be much appreciated by the profession and of great value for future reference. Dr Baile, the medical officer of health, returns to the subject of the serious condition of the milk supply. It is probably not worse than in other towns, but he reiterates his complaint that there is no control over the dairies outside the borough. Of the 358 samples examined from farms outside the boundary, 49.4 per cent conformed to the standard of Grade A of the English Ministry of Health, and 67.4 per cent out of 92 samples produced in the city. Inspection of town dairies has been followed by an improvement in the bacterial content of milk and in the hygiene of the dairy. Why should not inspection of outside dairies be obligatory? Dr Baile urges a uniform system of inspection for Northern Ireland.

The annual report of Dr Trimble, chief tuberculosis officer for Belfast, contains further information about this scourge, 2,023 new patients were examined during the year, 825 were found not tuberculous, but a third of them were living in contact with tuberculous patients. There were 31,596 reattendances on old cases, and at the end of the year 2,047 were receiving treatment at the Tuberculosis Institute, and 2,373 at their own homes. Dr Trimble says that of 1,237 cases of pulmonary tuberculosis examined during the year, over 40 per cent were probably infected by personal contact, 235 gave a history of the disease in either father or mother. He lays emphasis on the danger of infection being carried by food and table utensils. Only 228 had separate sleeping accommodation. The incidence of the disease in the different wards of the city differs much and follows the law found in other large cities, the more closely populated and poorer the district the larger the incidence, it varies from only 34 in the Windsor district to 219 in Pottinger. Excellent work was done at the Municipal Sanatorium and at Graymount Open-Air Hospital School. Attention is drawn to the encouraging figures which show that in Belfast consumption has been reduced by 30 per cent in 10 years, by 55 per cent in 20 years, by 62 per cent in 30 years, and by 68 per cent in 40 years.

MEDICINE IN ANCIENT IRELAND

An article in the Dublin *Evening Herald* on the science of healing in ancient Ireland mentions that the physician of those days ranked with the higher craftsmen and the workers in the precious metals. The book of Glendalough states that, in that famed locality, a separate seat was assigned him at the royal banqueting table. Under the

Brehon laws the haigh (leech) was entitled to his food and that of four of his pupils at the house of his patient while the latter was being healed. If the patient, however, was suffering from wounds caused maliciously, then the transgressor bore the cost. But should the wounds break open within a certain time the leech was obliged to refund his fees, these to be given to a better physician, who was able to keep the wound healed beyond the time prescribed by the test. This test was a year for a wound of the hand or arm, a year and a quarter for one on the leg, and three years for the perfect cure of a wound on the head. After this period neither the man who inflicted the wounds, nor the doctor who cured them, was held responsible for any after consequences. It was by no means uncommon for the tribe to make a grant of land to the physician, so that—in the words of the Brehon Code—he might be preserved from being disturbed by the cares and anxieties of life, and enabled to devote himself to the study and work of his profession. In the Brehon laws a distinction was drawn between the lawful and unlawful physician. If an unlawful physician removed a joint or sinew without obtaining an indemnity against liability to damages, and with a notice that he was not a regular physician, he should be subject to a penalty with compensation to the patient. The laws against quacks were very drastic. The value of cleanliness, pure water, and free ventilation seems to have been fully appreciated by the medical men of ancient Erin. Under the provision of the Brehon laws the doctor's house was the appointed place where the sick were to be treated. These houses were ordered to be built either on the bank of a running stream or with such a stream passing through the precincts. The building was to be provided with four doors, with the object of allowing all that took place within it to be open to inspection, and, further, to permit one door being left open whichever way the wind blew.

India.

THE HAFKINE INSTITUTE

On the suggestion of Lieut-Colonel F. P. Mackie, director of the Bombay Bacteriological Laboratory, it was decided on July 21st by the Government of Bombay that this laboratory shall henceforth be known as the Hafkine Institute. In proposing this change, Lieut-Colonel Mackie pointed out that the laboratory was started in 1896 by Professor Hafkine, C.I.E., for the preparation of his plague prophylactic, it was then housed in a small building in Bveulla. The work rapidly increased, and in 1899 the laboratory was moved to the position it occupies now in Old Government House, it was renamed the "Plague Research Laboratory." Later, in 1905, the work of a provincial laboratory was added to that of plague research, and in the following year it received the title the "Bombay Bacteriological Laboratory" to cover its wider function, which includes plague research and diagnosis, an antirabic unit, a biochemical unit, and a pharmacological unit for the study of indigenous drugs. Since its establishment over twenty-five million doses of plague prophylactic have been issued.

RABIES IN SOUTHERN INDIA

Lieut Colonel J. W. Cornwall, director of the Pasteur Institute of Southern India, Coonoor, deals in the annual report of the institute with the antirabic work performed from March 1st, 1924, to February 28th, 1925. Treatment was given during the year to 489 patients—a decrease of 865 on the number for the previous year. This decrease was due to the area served by the institute having come under the operation of the new system, whereby antirabic vaccine is issued to numerous centres for local use. At these local centres during the year the number of persons who were treated was 4,402. Until nearly three years ago all those who desired antirabic treatment in Southern India had to travel to Coonoor to obtain it. Continuing the research work of the last twelve years, the director reports

that about 33 per cent of untreated persons died from hydrophobia who had been bitten by dogs proved to have been infective at the time of biting. Additional evidence was obtained that not all rabid dogs are infective at the time of biting, and that the risk of death from hydrophobia following the bite of an infected dog is not more than 33 to 100 even without treatment. In the period 1907 to 1924 30 253 persons were treated at the institute of whom 45 died during the treatment, either having received in beginning it or having been the victims of unusually brief incubation periods. Apart from these 45 a full course of treatment was given to 30,208 patients of whom 295 died subsequently from hydrophobia, the case mortality being thus 0.97 per cent.

MALARIA AND AGRICULTURE IN BENGAL

In a report published by the Public Health Department of the Government of Bengal Dr Charles A Bentley, director of public health in Bengal, adduces a considerable weight of evidence in favour of his contention that malaria in Bengal may be diminished by irrigation, and that the agricultural conditions will simultaneously be much improved. He finds that the delta areas are relatively healthy and very prosperous so long as they remain subject to normal inundations by the rivers. He believes that the network of embankments which have grown up in the country in connexion with roads and railways has interfered with the normal irrigation to a serious extent, and has been an important factor in causing epidemic malaria during the last and agricultural decline in lower Bengal during the last sixty years. The antimalarial projects he suggests are based upon the principles which underlie the Italian "Boniferaione." Agricultural drainage schemes in many cases seem to have done more harm than good in Bengal, and it is claimed that irrigation, rather than drainage, is the immediate need. Although the Eden canal project, and the Midnapore project—appear to have failed in this respect, an increase of malaria having followed, yet Dr Bentley shows that in both cases these systems do not allow of a large supply of water for flushing the fields during the flood season irrigation being restricted to the early and late parts of the season. The October irrigation which is provided cannot be effective in reducing mosquitos in the time the majority of malarial conditions which permit them to develop to the best advantage, the breeding places have already been produced under conditions. Flush irrigation not being exposed to effective water flushings. Flush irrigation is practised in the Madras deltas has not been found to increase the malaria incidence, but on the contrary, to render the areas using it less liable to the disease. Dr Bentley concludes that the irrigation required in Bengal for the total purpose of improving agriculture and reducing malaria must be of this flushing type, utilizing the largest possible amount of water that can be withdrawn from rivers during, and not after, the flood season, the aim must be to raise the subsoil water level, keeping it as high as possible during the wet season so as to benefit the crops and reduce malaria. He recommends that every possible encouragement should be given to public bodies, voluntary institutions, and private individuals to push forward irrigation projects, including the construction and restoration of lands of watercourses, and the protection of river channels generally. He pleads for the appointment of an irrigation commission for Bengal empowered to obtain the views of irrigation experts familiar with all types of irrigation practised in India, Egypt, Syria, and elsewhere. There is, he says, cultivable land in the Burdwan and Presidency divisions equal in extent to the whole of the cultivable land in Egypt, but which is now lying waste for lack of the necessary irrigation water. Yet the very flood water needed for the growth of the country is actually passing to the sea unused being confined by embankments to river channels such as the Padma the Ganges, the Damodar and smaller streams. Rectification of this condition would increase the alluvial storage of Bengal, and restore the flow during dry weather in old watercourses, thus reducing malaria and benefiting cultivation.

Correspondence.

PROPOSED MEMORIAL TO THE LATE HAMILTON DRUMMOND

SIR,—The tragic death of Mr Hamilton Drummond is so fresh in the minds of his friends that it is unnecessary to detail the circumstances of that calamity. He was so well known and so greatly beloved by those in all walks of life that it is felt that some memorial should be promoted.

A committee of his colleagues on the staff of the Newcastle Royal Infirmary, together with some non medical friends, has been formed for the purpose of carrying out this object. It is proposed that the memorial should be connected with the Newcastle upon Tyne Infirmary and the Medical School which he served so faithfully, and in which he was so much interested. The exact form of the memorial must be decided at a later date and will largely depend upon the amount subscribed.

The committee has decided to appeal for subscriptions up to a limit of five guineas, but it is hoped that all who cherish his memory will subscribe, irrespective of the amount.

Professor R P Raulen Lyle and Mr E Philip Noble have been appointed joint treasurers. Subscriptions may be sent to the former at 11, Osborne Terrace, or to Mrs Lloyds Bank, Ltd, Grey Street, both in Newcastle upon Tyne, or to any of the undersigned.—We are, etc,

THE SOCIETY OF RADIOGRAPHERS AND THE INSTITUTION OF ELECTRICAL ENGINEERS

SIR,—With reference to the withdrawal of the representatives of the Society of Radiographers, which was mentioned in your columns on August 1st, 1925 (p 239), I think that a rather fuller explanation of the position of the society is desirable than was there given. At a meeting of the council of the society in June, 1924, it was unanimously agreed that the proposed new rules preventing any report or diagnosis on any radiogram or screen examination should be interpreted to allow a radiographer (in the absence of a medical radiologist) to describe to a medical practitioner the appearances seen in an x-ray examination, so as to assist him in making a diagnosis. Later on at the same meeting the representatives of the Institution of Electrical Engineers, moved that the resolution so amended should not be applicable to any

members of the society, who, on January 1st, 1924, had been engaged in a ray work for not less than fifteen years. Such members would thus be allowed to interpret radiograms, make screen examinations, diagnoses, and treat patients. On July 28th, 1924, objection was taken to this radiation by the General Medical Council, who pointed out that if such a clause was inserted in the rules the medical members of the society would find themselves in the untenable position of associating with unqualified persons who were performing medical functions without medical training or without immediate personal supervision. This decision of the General Medical Council the medical members on the council of the society could not, of course, dispute, but the representatives of the Institution of Electrical Engineers maintained their support of the clause in question. A very large proportion of the radiographers, however, expressed agreement with the suggested new clause. The Institution of Electrical Engineers thereupon withdrew their members from the council of the Society of Radiographers. The reason assigned for this withdrawal in the announcement in the *BRITISH MEDICAL JOURNAL*—namely, that the status of the non-medically qualified radiographers would be materially lowered by the new rule—hardly seems to be justifiable, especially as radiographers have requested almost unanimously in it, despite the omission of the clause proposed by the institution—I am, etc.,

London W 1 Oct 17th.

STANLEY MELVILLE

OSTEOPATHY AND CHIROPRACTIC

SIR,—When a new sect in medicine arises the attitude of the profession toward it is important if it seems to have any germ of truth its pretensions should be examined, as happened in a recent case. If it seems destitute of truth and reason it should be ignored, for opposition only acts as a stimulus. In the present case I see no reason for an examination, for the movement seems not only to be "beneath notice but beneath contempt" (a phrase used by the late Dr. Gec on a different occasion), and surely it is destined to die by its own inanity—I am, etc.,

Wind or Oct 18th

W F LLOYD

SIR—I have read with much interest Sir Holburt Waring's paper (*BRITISH MEDICAL JOURNAL*, October 17th, p. 679) in which he points out the fallacies in the theory of osteopathy and chiropractic.

It is true that, although on paper the osteopathic course is as strenuous as that of medical students in the United States of America in practice some of the schools are very lax in the conferring of their degrees. On the other hand, there are some schools in which the work is done with thoroughness. Moreover, a fair proportion of the osteopaths practising in this country have a medical degree in addition to their osteopathic qualification. It is a pity that some distinction cannot be made.

There is one matter which should carry weight before the medical profession: namely, osteopathy and chiropractic entirely, and that is that if a patient is sick he does not mind what theory there is at the back of the treatment he receives, but he wants to be made well. If, after the general practitioner and the specialists have failed to relieve him, he drifts out of the fold, and is promptly cured by an osteopath or other unqualified man, this is a blow to the confidence he has had in the medical profession.

As a matter of fact, I can affirm that I have seen some scores of cases—and not merely "functional" cases, but of the sort with definite physical signs—which have been relieved by osteopathic manipulations when other treatment had failed, with the disappearance of these physical signs. Needless to say, these were cases of a mechanical nature, and not infective.

Of course, it is nonsense to claim, as do some, that the cure of all and every disorder lies in the ten fingers. But by a careful investigation into the practice (and not merely into the theory) of osteopathy, we should certainly find that there is some grain among the chaff, and that that grain might well be incorporated in our therapeutic

armamentarium. Certainly, some serious mistakes have been made, but osteopaths are not the only ones who have been known to treat appendicitis, abscesses of tuberculous joints in the wrong manner. We all of us make mistakes at times, and this alone should not be the cause of the discrediting of any system which can claim such successes as osteopathy has at times achieved—I am, etc.,

Leeds, Oct 18th

L J BENDIT, M A, M R C S

SIR,—In your leading article on osteopathy and chiropractic (October 17th, p. 708) you state "We feel sure that the medical profession at large will endorse the opinion expressed by Sir Holburt Waring that 'instead of the Legislature making possible the licensing of osteopaths in a very limited form of practice, the Medical Acts ought to be so strengthened that it would not be possible for the community to be treated by them or any other unqualified charlatan or quack.'"

Sir Holburt's opinion is practically the substance of the motion by St. Helens and Warrington, which was brought before the Representative Body at Bath in July, yet in the issue of August 1st (p. 222) you write "Of the more important motions from Divisions, that from St. Helens and Warrington on unqualified practice was dealt with on sound lines on Dr. Hawthorne's lead." The "sound lines" were the relegation of the motion to the safe deposit of the waste-paper basket, that being in essence the meaning of Dr. Hawthorne's motion to pass to the next business. Why this rapid change in the editorial attitude?—I am, etc.,

Warrington Oct 16th

J S MARSON

** Our attitude has not changed. The Warrington motion, as we understood it, sought to secure by the action of the medical profession an amendment of the Medical Acts so that "no unregistered person be allowed to practise medicine or surgery." Dr. Hawthorne argued that this motion was unsuitable to be put forward in a meeting of medical practitioners, on the ground that such amendment of the law should be pressed upon the Government by the citizens of the country rather than by medical practitioners. The passage quoted from Sir Holburt Waring's address referred to the contention by osteopaths and chiropractors that they should receive a partial licence to practise—a demand shown by us, in a leading article on April 11th, 1925 (p. 706), to be inadmissible. We agree with Sir Holburt Waring that the law against quackery ought to be strengthened, but, in agreement with Dr. Hawthorne, we think that this strengthening is more likely to be brought about by the pressure of an enlightened public opinion than by direct action on the part of the medical profession. It is a question of the best means to the end in view.

HAEMOGLOBINURIA DUE TO COLD

SIR,—I am very much obliged to you for the review of my work *Studien über die Kältemoglobinurie*. Allow me at the same time to make the following explanations.

1 My view that haemoglobinuria due to cold is, in all probability, invariably a sequel to syphilis is based on special studies on this subject, which have only just been published. In my above mentioned work this view was advanced with reference to my then forthcoming paper.

2 It is stated in the review that there is a certain ambiguity in my classification of haemoglobinuric patients, and that the classification on page 657 is not the same as that on page 623. The four different modes of reaction summarized on pages 623-624 are those which were observed during the experimental period in Case L there discussed. It should be noted that, as is clearly shown, the first and second modes of reaction are merely gradational variants of the same mode of reaction. In the general classification which follows on page 657, both these variants have therefore been combined into a unified group "first mode of reaction." In both classifications modes 3 and 4 are identical in that order. In addition to the modes of reaction described on pages 623-624, I have, however, added in the general classification (p. 657) yet another mode—namely, that given as No. 2 "Intravasale Sensibilisierung und

Hämolyse, kein Schock" In the following paragraph (p 657) I point out, however, that "Keine Reaktion nach Modus 2 ist nicht sichergestellt, vielleicht kommt dabei immer eine leichte hämolytische Krise vor" In regard to the existence of this form of reaction, my views, as I had previously pointed out, are based not on my own observations but on data furnished in the literature of the subject.

3 It is further stated in the review "Patients with manifest haemoglobinuria fall into the two first classes, the latent into the last two."

This is a misinterpretation, for, as is made clear in the last paragraph on page 657, the statement should read "Patients with manifest haemoglobinuria fall into Classes 1-3, the latent into Class 4."

Trusting that you will not take it amiss that I have made these observations, I beg to thank you for the friendly interest which you have shown in my work.—I am, etc.,

FRIEST SATIN

INFECTED MYOMA COMPLICATING PREGNANCY

SIR,—In the report of his case under the above heading (BRITISH MEDICAL JOURNAL, October 10th, p 647) Dr H R Spencer does not give the reasons, either clinical before operation, or any evidence noted at the time of the operation, which decided him to perform hysterectomy instead of myomectomy with preservation of the uterus. If this information can be added to his report it would be extremely valuable to those who may at any time be in charge of a similar case but without the advantage of so large an experience as Dr Spencer's.

One is encouraged to ask for this further evidence, as the statement is made in the paper that "it is well known many necrobiotic fibroids are sterile and can be removed with safety", and Dr Spencer goes on to point out that a rapid bacteriological examination during the operation is desirable, but perhaps would not be obtainable.

In this aspect of the matter—that is, hysterectomy as against conservative myomectomy—the case where total removal of the uterus is forbidden in advance by either the patient or her husband, unless there is *acute infection*, for reasons of important family succession, for instance, must be remembered, and renders all possible information on the differentiation of infected fibroids from sterile before removal most desirable.—I am, etc.,

Notwich Oct 12th

ARTHUR CROOK

MYXOEDEMA

SIR,—In your issue of October 10th (p 657) you publish an annotation under the heading "Myxoedema." In it you state, "George Murray was able, in 1891, to cure such a case by injecting a glycerinated extract of the gland—a method soon to be abandoned when it was shown by Howitz in Denmark that results were equally good and infinitely easier to obtain by oral administration of the gland."

In your issue of October 29th, 1892, you published an annotation, under the heading "The treatment of myxoedema." There you stated, "It would seem not only that there is no doubt of the efficient action of the gland when taken by the mouth, but even that some care must be taken not to let the patient swallow too much of it." You based this information on the account of two cases published in the same issue—one by Dr Hector Mackenzie and one by myself.

To credit the fact that oral administration of thyroid gland is to-day universal and due to work done in Denmark, seems to me to belittle the utility of your own journal, and to endow a foreigner with what might more justly have been given to Englishmen.—I am, etc.,

L L FOX

THE SURGEON AND THE PUBLIC

SIR,—While many of the points put forward by Mr E R Flint in your issue of September 19th (p 540) will receive the support of all medical men, some are open to controversy.

Educating the public by broadcasting, etc., on the methods of attaining and maintaining health may do good,

though people will probably pay as little attention as they do to other forms of teaching. Bringing before them the early signs and symptoms of disease is another matter, the main objections to this were put forward in my letter published in the JOURNAL of June 13th. The neurotic will ponder over such advice with the assiduity they now do such works as "Medicine for the Million," and with their inexperience will find good ground for all their morbid fears. Our race is losing much of its old stolidity, and the chronic infections and viscerophtosis are on the increase. It is difficult enough now to convince sufferers from the latter that the removal of an appendix or the fixing of a mobile kidney will not cure their complaint. Were they to be acquainted with the symptoms of gastric and intestinal cancer, they will be unable to distinguish between these and their own functional symptoms, and nothing short of a laparotomy will suffice. Otherwise they will proceed to the quack, who will not fail to profit by curing such "definite" cases of the disease. This is only one of the dangers, others are equally obvious.

Much might be done by impressing upon the public the necessity of calling in a doctor immediately they feel ill, rather than in first trying household remedies. But many of our most serious diseases are very insidious in their onset. The only possibility of diagnosing these in the earliest stages is by inducing the public to undergo a medical examination at least once a year. For this to be of value we must have a profession that is not only conversant with the earliest signs of disease, but is also aware of methods of diagnosis which are valuable when suspicious symptoms are present.

The holding of a resident appointment and post-graduate instruction are essential for the practitioner. But the root of our present trouble lies further back—namely, with our system of examinations. One of the primary aims of medical education should be that the newly qualified man is not in agglomeration of embryonic consultants, but is well instructed in the fundamentals of general practice. It is our rule in the surgical unit here when demonstrating a case to point out, not only the physical signs, but to go back over the history and lay stress on the earliest symptoms with the signs that might have been found and the methods of diagnosis that should have been carried out. It is our impression that, when the students leave the wards they have been instilled with that which should be common to all medical men—the necessity for and means of early diagnosis. Later these same students have to be prepared for their examinations. And it is a sad sight to see men, who at one time viewed their work with a practical outlook, becoming converted into automata of classifications, biochemical facts, bacterial strains, obsolete splints, etc. When I have discussed this aspect with examiners, they have generally been sympathetic, but have pointed out that such a course is necessary for a good scientific training. This being the case, one surely should not blame these students for failing to diagnose when later they go into practice. Some alternative should be possible. I would put forward the suggestion that an examination similar to the present final should be held at the end of the fifth year, the passing of which would merely allow the student to enter on work under the supervision of a fully qualified man, the first two months could be spent attached to a general practitioner, the last four as an assistant to a hospital resident. At the end of this time the examination for the diploma could be taken, this being essentially practical and dealing with such problems as the early signs of disease, methods of diagnosis, treatment, etc. Such a course would mean that the last six months, instead of being wasted in the coaching classes, would be spent at the bedside dealing with points of practical value. It would have the added value that, should general practice be the aim, the student would have some idea of the work in view, and would be able to think accordingly during his last months in hospital.

It is obvious to all that things are not right with medicine. If, however, any reform is needed, it is better that it should come from within the profession rather than be forced upon us from outside.—I am, etc.,

T L HARRISON

Cardiff Sept 28th

A FRENCH VIEW OF FREUDISM

SIR,—May I claim a little space in which to reply to your two correspondents, Dr Arthur Lynch and Dr Charles Buttar, both of whom leave me entirely unrepentant. To my mind the doctrine of a dynamic unconscious provides the only scientific explanation of the origin and symptoms of a neurosis, and my contention is that students should be taught to recognize a neurosis is the outcome of repression and conflict. Once it is realized that a neurotic patient is an interesting problem and not simply a nuisance, we shall have many more investigators in the field, and much which now stands in need of elucidation may be made clear. Individual workers will tend to stress some one factor and some another, but all will have their successes, if they approach each case with unprejudiced minds.

I have my own opinion as to whether the stool of Freud will rise or fall in the market eventually, but I have little patience with those who refuse to give any measure of credence to psychology because they cannot agree with him. I have never been able to ascertain what treatment a functional case receives from those who scorn psychology. True they can, and do, order the patient a rest and a change of air, but *coelum non animum mutant*. We claim to change the "animum" in no inconsiderable proportion of cases. Dr Buttar must have been singularly unfortunate in his experiences. As his "terror" is acknowledged and not repressed, I trust he is feeling no further ill effects from the perusal of my former letter.—I am, etc.,

R MACD LADLE

THE TEACHING OF PHYSICAL TRAINING

SIR,—In the JOURNAL of October 3rd (p 608) is an original contribution by Surgeon Commander H B Hill on common mistakes in the teaching of physical training. The points he raises are of considerable importance to everyone interested in the physical development of the growing generation, either from the point of view of training the normal individual, or, like myself, more from the point of view of preventing and correcting faulty development.

I fail to see the reason for the author's sweeping statement that no breathing exercise should be done simultaneously with any movements of the arms or other part of the body. It is certainly true that exercises involving strong contraction of the abdominal muscles interfere with the action of the diaphragm and thus impede the respiration. Such exercise ought therefore to be followed by some breathing exercise to counteract this effect. On the other hand, I have failed to notice "the severe restriction to breathing which takes place when the arms are moved and the head pulled back," which, the author says, "can be watched by anyone." To me it seems that head bending backwards and arm liftings which bring the auxiliary respiratory muscles into work, and thus raise the ribs and enlarge the thorax in the upward and antero-posterior direction, facilitate deep inspirations, whereas the raising of the head again and the lowering of the arms by relaxation of the muscles favour expiration. I see, therefore, no reason why these movements adapted to the rate of normal respiration should not be used as breathing exercises.

Surgeon Commander Hill's remarks on the straight spine are much more in accordance with my own views. His definition of the medically straight spine—"one which gives an erect carriage to the body, has all its natural curves in correct proportion to one another, and is quite free from any lateral curve"—seems to me an admirable one. To achieve such an ideal in the way of carriage, the individual should be taught to aim at cultivating "a long neck" as the old slogan says. Therefrom follows in a marked manner a correct poise of head, shoulders, and chest.

I quite agree with the author about the deplorable result on the figure from an undue protrusion of the chest at the expense of a lordosis in the lower part of the spine.

I am less in agreement with regard to the author's opinions on leg exercises. The only fact that seems to me amply confirmed by his remarks is that great confusion exists on this subject. I still believe in the efficacy of such exercises at the right time and of the right type in

"deflecting the blood" to the lower extremities, and thus relieving congestion to the head and thorax after powerful trunk exercises, especially if involving stooping, and that they have a calming effect upon the heart and respiration, but no sensible poison, I should have thought, would be likely to advocate further leg exercises as an antidote after a cross-country run. The choosing of such an example as an argument against the judicious employment of leg exercises in order to relieve congestion and quieten the heart, illustrates best the state of confusion referred to.—I am, etc.,

London W 1, Oct 6th

RICHARD TIMBERG

"THE STRAIGHT SPINE"

SIR,—May I, as one who is in his 60th year, and is to day physically and mentally a much fitter man than he was some twenty years ago, be allowed to make some remarks on the interesting article by Surgeon Commander Hill, R N, "Common mistakes in the teaching of physical training."

Surgeon Commander Hill says, "The medically straight spine is the one which gives an erect carriage to the body, has all its natural curves in correct proportion to one another, and is quite free from any lateral curve." The italics are mine.

This is certainly the spine usually seen in the average so-called healthy human being, but it is not the spine we see in a runner who is going strong with his "second wind." It is true his body is slightly inclined forward from the hips, but the chin is in line with the body and the spine is kept fully extended. There is no curve in the lumbar region or elsewhere: the back is quite flat. The same is true of the properly trained walker. And, as we all know, rowing men are taught to "keep a straight back."

I do not know whether my vertebrae are piled evenly on top of one another like a child's single column of twenty-four bricks, as shown in diagrams illustrating what Surgeon Commander Hill terms "a faulty spine." But I do know that my spine can be held apparently straight without any strain, by making proper use of the muscles governing the erect posture.

When I am sitting on the floor, or on a stool, with my back against the edge of an open door, the small of my back, spine, and back of my head are against the door. When standing up against a straight edge with the heels touching the edge—say of an open door—my spine and back of the head are still pressed against it. The same is true when I am lying on the floor at full length: the heels and the whole of the spine from the sacrum to the back of the head are on the ground. Any man, woman, or child who has muscles of normal average length, flexibility, and strength, and knows how to control them, can do the same easily when sitting, standing, walking, or running. The trouble with most of us is that we do not possess the much to be desired quality of muscle, nor the knowledge necessary to make proper use of them, so the spine settles down into curves.

Some twenty years ago my attention was drawn to the influence on health of a straight spine through reading Dr Latson's book *Common Disorders*, and *A Natural Method of Physical Training*, by Edwin Checkley. The result of the daily practice of the exercises described and illustrated in the above works, as well as some others based on the principles advocated by these two writers, has been most beneficial to me, as well as to many of my patients.

In my own case, not only was my spine straightened out as fully as possible, enabling me to make the most of my height, but the flexibility of my body, breathing powers, and general health were also vastly improved thereby. When I first took myself in hand my vital capacity, as measured by the spirometer, was only 200 cubic inches. In due course it went up to 340 cubic inches (a gain of 140 cubic inches), which is only 10 cubic inches less than it was when I was a young man of 25, well over a quarter of a century ago. My vital capacity, taken six months ago, still registered 340 cubic inches, and I am remarkably fit and well to-day.

So it seems to me that human beings who have cultivated

URBAN PRITCHARD, F.R.C.S. Ed., F.R.C.S. L.S.A., F.R.C.S. L.R.C.P., L.S.A. in 1868 and 1869, he then went to Edinburgh, and graduated there M.B., C.M. in 1869 and M.D. in 1871, being Little's Scholar, and winning the gold medal. In 1872 he obtained the F.R.C.S. diploma on return to London in 1870 he was, what was then the "Assistant" to Sir George Johnson at King's College Hospital, and afterwards to Sir George Johnson at the Royal Ear Hospital.

URBAN PRITCHARD, F.R.C.S. Ed., F.R.C.S. Eng.
Emeritus Professor of Aural Surgery, King's College Hospital
Consulting Aural Surgeon, the Royal Ear Hospital

In his 81st year Professor Urban Pritchard, the doyen of otology, has passed away. He was the fifth son of Andrew Pritchard, F.R.S. Ed. He received his medical education at King's College Hospital, and obtained the qualifications M.R.C.S., L.R.C.P., L.S.A. in 1868 and 1869, he then went to Edinburgh, and graduated there M.B., C.M. in 1869 and M.D. in 1871, being Little's Scholar, and winning the gold medal. In 1872 he obtained the F.R.C.S. Eng. diploma.

On his return to London in 1870 he was, what was the "assistant" to Sir George Johnson at King's College Hospital, and later on, he became a consultant in ear, nose and throat.

On his return to London in 1870 he was, what was the 1
called, "physicians' assistant" to Sir George Johnson,
Dr. Lionel Beale, and Sir Alfred Garrod at King's College
Hospital, later becoming surgical registrar and lecturer
of the museum. Being keenly interested in physiology,
he was appointed demonstrator of physiology and lecturer
on physiology for the evening classes at King's College
All this time he was making researches into the auditory
labyrinth especially in connexion with the organ of Corti
He then turned his attention to diseases of the ear, and
was appointed surgeon to the Royal Ear Hospital in 1874,
then the only institution of its kind, a position which he
held until 1900, when he retired from it being made
consulting surgeon. In 1876 he became the first aural
surgeon to King's College Hospital and professor of aural
surgery in King's College in 1886. On his retirement in
1910 he was made consulting aural surgeon to the hospital

Between 1876 and 1881 Urban Pritchard published four papers as a result of his original researches into the origin of Corti, based on his own microscopic sections, which, considering the method of preparing them which then obtained, were of great beauty, and bear examination to this day. This work became well known. The first paper is entitled "The organ of Corti in mammals," and a paper in the Royal Society, and it is interesting to note that the then secretary, Professor

and eminent professor of anatomy. He had been in London as a matter of fact, he was a singer in Great Britain. Urban Pritchard published four papers as a result of his original researches into the origin of Corti, based on his own microscopic sections, which, considering the method of preparing them which then obtained, were of great beauty, and bear examination to this day. This work became world famous. The first paper was entitled "The organ of Corti in mammals," and was read before the Royal Society, and it is interesting to note that he was introduced by the then secretary, Professor Huxley. It was published in the *Proceedings* (1876) and it has made many original observations on the structure of Corti. He made many original observations on the structure of Corti. He supported Helmholtz's theory, with the modification, development, and function of the modification that the rods are concerned only indirectly, and that their vibrations affect the hair cells connected with the nerve filaments to the brain, and he considered it highly probable that the graduation in length of the variation in account for the appreciation of the variation considerable extent, and "he could not believe for instant the rods and rest of the organ were so beautifully graduated for no special purpose." To show the amount of work done, he states that he had examined the organs of man, monkey, sheep, dog, cat, rat, guinea-pig, porpoise, and langur. The other three papers were "Termination of nerves in the vestibule and semicircular canals," "Quarterly Journal of the origin of Corti," "Development of the organ of Corti," "The cochlea," "Physiology, 1878," "The cochlea compared with mammal," and "The cochlea compared with the Royal Society."

Termination of nerves in the
cords," *Quarterly Journal of the*
1876, "Development of the organ of Corti,"
Anatomy and Physiology, 1878, "The cochlea and
Omnithorhynchus platypus compared with mammals and
birds," *Philosophical Transactions of the Royal Society*,
1881 In the last paper he described the presence of the
lagena in the *Omnithorhynchus platypus*, which is also present
in birds and not in the ordinary mammals, the lagena
is an enlarged interior extremity of the cochlea tube, with
a modified lining and a large patch of nerve epithelium,
quite distinct in structure and separate from the organ of
Corti, this nerve epithelium being made up of cells exactly
like those found in the macula acustica of the vestibule
of mammals and birds, and he notes it is another of the
many links between the bird and mammal in this mono-
treme He also points out that the birds' cochlea is similar
to that of reptiles and amphibians, and therefore the lagena
is really a link between the cochlea of the higher and
lower vertebrates, and not merely between that of the
mammal and bird
From that time his purely scientific work came to
an end, and his life being taken up by clinical work
with his very large private practice, and his patients, a

mammal and bird

From that time his purely scientific work came to an
end, the rest of his life being taken up by clinical work
in the hospitals and by a very large private practice, in
which he was trusted and loved by his patients, and in
which he was trusted and loved by his object, and in
rightly so, for their good was clearly visible to them His work
perfect uprightness was clearly visible to them His work
and personality were well known and appreciated throughout
the civilized world For many years—from 1884 to 1892—
he was the chief British representative on the Committee
of Organization of the International Congress of Otolaryngology,
which meets periodically in different countries, and when
it became Great Britain's turn, in 1899, he was elected
president It met in London, and it may be said that,
owing to his scientific work under his presidency, a re-
naissance of British otitis surgery took place He
attended and took part in the business of the Congresses,
held in Paris, as late as 1922 As a direct result of the
London Congress, the Otological Section of the United
Kingdom, now the Otological Society of the Royal Socie-
ty of Medicine, was formed, he was its second president, and
never ceased to take part in the meetings He never lost
his mental elasticity, and was always ready to appreciate
and foster advances and to act upon them From 1890
to 1908 he was co-editor of time to write a Handbook of
Otology, and also found time to write three editions
Diseases of the Ear which ran through three editions
Urban and Schwarzenberg deserved well of the profession and his
country His domestic life was a particularly happy one
In 1872 he married Miss Blanche Pallister, and they celebrated

his mental elasticity, and to act and foster advances, and to act to 1908 he was co-editor of the *International Otology*, and also found time to write a *Handbook of the Ear* which ran through three editions. Dr. Urban Pritelard deserved well of the profession and his country. His domestic life was a particularly happy one. In 1872 he married Miss Blaine Pallister, and they celebrated

their golden wedding in 1922. His wife, one daughter, and two sons (one of whom is in the medical profession) survive him, to whom we offer our profound sympathy.

ARTHUR H. CREATIE

P. R. COOPER, M.D., F.R.C.S.,
Consulting Surgeon, Altrincham General Hospital

A CLOUD of sorrow has been cast over Altrincham and the district of North Cheshire by the news of the death of Dr Percy Cooper, who passed away on October 10th in a Manchester nursing home, where he had been lying ill for eight days suffering from blood poisoning.

Percy Robert Cooper was the elder son of P. B. Shelley Cooper of Lymm, Hyle. He won a scholarship at the Manchester Grammar School in 1882, but two years later his uncle wished him to go into the cotton trade with him, and he left school to do so. While he was in business he used to attend science lectures at Owens College, Manchester, in the evening, and this gave him the desire to enter the medical profession. Upon leaving business he studied medicine at Owens College, taking first-class honours in his B.Sc. examination in 1890. He graduated M.B., Ch.B. in 1893, and in the same year took the diplomas M.R.C.S. Eng., L.R.C.P. Lond. He later joined St. Bartholomew's Hospital, London, obtained the F.R.C.S. Eng. in 1895, graduated M.B. with first-class honours in the following year, and proceeded M.D. in 1901. After holding a resident post at the Royal Infirmary, Manchester, he gained some experience of family practice in Halmesley, and undertook research work in cancer at Owens College. Not long afterwards he began practice in Altrincham. For some time he was a consultant in Manchester, but he relinquished this work after the war. He gave great assistance to the local Red Cross hospitals, and the hard work he did in this direction undoubtedly tried his health. He was a past-chairman of the Mid Cheshire Division of the British Medical Association and of the Altrincham Medical Society. He had been chairman of the Clinical Society of Manchester, he served on the committee of the Manchester Medical and Pathological Society, and was chairman of its library committee.

In his early life Dr. Cooper played Rugby football for the Victoria University for three years. He also took an active interest in golf, winning the gold medal and cup of the Manchester Medical Golfers' Society, he was the winner of the captain's cup of Timpersley Golf Club, and secured many other prizes. As a member of the honorary surgical staff of Altrincham General Hospital he took keen interest in the x-ray department, and presented to it an artificial sunlight lamp. He was also widely known as chairman of the executive of the local branch of the League of Nations Union. He was an active member of the Local Medical and Panel Committee of Cheshire on which he was co-opted to represent the non-panel practitioners. He will be well remembered for his advocacy of "payment for work done" before the passing of the Insurance Acts, being a frequent contributor to the columns of the *BRITISH MEDICAL JOURNAL* and other professional journals.

A large number of medical men and other friends assembled at the Manchester Crematorium to mark their respect for a life so rich in scientific knowledge, so full of achievement, and so untimely ended.

A Manchester colleague writes: "It is impossible to express in words the vastness of the loss to our profession in general, and to those of us who have had the honour of his friendship in particular, which results from the tragic death of Dr. Cooper. Within my memory, at any rate, there has never been in this area a medical man more universally admired and respected by his fellow practitioners or more sincerely trusted and beloved by his patients. His wonderful enthusiasm in his work, his intense interest in the welfare and progress of medical science, and the efficient way in which he ever kept himself abreast of its very latest developments, made us all appreciate as a very great honour the occasions when he sought our help in consultation."

News has been received of the sudden death, on September 16th at Townsville, North Queensland, of Dr. Ernest Humphry, honorary surgeon to the Townsville Hospital. For the following note of his career we are indebted to Mr. R. F. Jowers, F.R.C.S., of Hove. Ernest Humphry, eldest son of the late F. A. Humphry of Brighton, was one of those deservedly popular men who, by their loyalty and comradeship, endear themselves to their friends. He was educated at Birdfield College, and on leaving there went to the Royal Sussex County Hospital as a pupil. In October, 1881, he entered St. Bartholomew's Hospital, where he rapidly became popular with both students and staff. Always keen on his work, he found time to enjoy his recreation, and played football regularly. At the end of his first year he took the anatomy prize, and eventually became house-surgeon to the late Sir Thomas Smith. Shortly after leaving the hospital he went to Australia, and settled at Townsville, Queensland, where he became honorary surgeon to the hospital. He soon gained a reputation as a surgeon, and up to the time of his death was doing a large surgical practice. He married an Australian lady, by whom he had two children, a son and a daughter, both of whom he married. After he had left England he had only once paid a brief visit to this country, about twenty-five years ago. There are still many who will recall his cheery ways and regret his death.

Dr. ADAM ROBERT HAMILTON OAKLEY, who died on September 26th, at the age of 69, received his medical training at St. Bartholomew's Hospital, and obtained the diplomas L.R.C.P., L.R.C.S. Edin. in 1882. After some experience as medical officer in the P. and O. Steamship Line, Dr. Oakley was engaged in medical practice at Hounchurich, Essex, and subsequently for many years at Hampstead. His post appointments included those of house-surgeon to Hertford Infirmary, and honorary anaesthetist to the London Throat Hospital. In 1914 he retired from practice, but during the war he held a temporary commission as captain in the R.A.M.C. In 1918 he was appointed medical inspector of schools under the Middlesex County Council, which position he retained until he finally retired in January, 1924. He leaves a widow and one daughter.

Dr. FREDERICK LANGLEY HUNT, C.M.G., superintending medical officer of Jamaica, who died on September 30th, while on leave in London, was born in 1856, the second son of the late Mr. L. Langley Hunt of Co. Limerick. He was educated at Cranichel College and the Royal College of Surgeons in Dublin, and took the diplomas L.R.C.P. and L.R.C.S.I. in 1884. He served as a civil surgeon with the South African Field Force 1899 to 1902, part of which time he was on the personal staff of the Commander-in-Chief, was twice mentioned in dispatches, received two medals and six clasps, and was awarded the C.M.G. in 1902. He was subsequently employed in the Anglo-German Boundary Commission to Lake Chad, and for his services received the thanks of the German Government and the Royal Order of the Crown of Prussia (third class). In February, 1905, he was appointed to the West African Medical Staff, and received the thanks of the Secretary of State for his services in connexion with the outbreak of plague at Aden in 1908. He was appointed inspecting medical officer and assistant principal civil medical officer at Ceylon in 1912 and 1915 respectively. He was transferred on promotion to Jamaica as superintending medical officer in 1919, which appointment he held at the time of his death. Dr. Langley Hunt leaves a widow and three sons. The funeral took place at Golders Green Crematorium on October 3rd.

Dr. LAWRENCE RYAN of Crumlin, who died recently, was born in county Limerick in 1866, and was educated at University College, Liverpool. He obtained the diplomas of the Conjoint Board in Scotland in 1887, and took up his residence at Crumlin some twenty-five years ago. He was a member, and at one time honorary secretary, of the Monmouthshire Division of the British Medical Association. In 1912 he was appointed a magistrate, and was elected

THE Court of the University of Wales, at its last meeting, adopted by 71 votes to 41 a resolution in favour of applying to the Privy Council for a charter incorporating the Welsh National School of Medicine as an independent school of the University on the lines of the draft scheme which had been before the University for the last year or more. It was, however, decided that before the petition was forwarded a conference should be held between the councils of the University of Wales and of the University College of South Wales and Monmouthshire.

The Nottingham Medico Chirurgical Society (founded in the year 1828) is one of the oldest medical societies in the country. The newly elected president is Mr. H. Bell Travers, who will take the chair at the first meeting on October 30th, when Sir St. Clair Thomson will give an address on "Dysphagia and some diseases of the oesophagus."

SHEFFIELD has obtained for its future hospital site Norton Park, which is 120 acres in extent, and is within twelve minutes' ambulance service of the centre of the city. Thanks to the generous gift of Councillor and Mrs J G Graves of Shoffield, an additional 154 acres of the adjacent estate has also been received, thus safeguarding the future voluntary hospitals of Sheffield from any industrial or residential building in their vicinity.

THE Fellowship of Medicine announces that on October 26th, at 5 30 p m, Dr Marcus Paterson will give the second lecture for the Fellowship of Medicine on the treatment of pulmonary tuberculosis, in the lecture hall of the Medical Society of London, 11, Chandos Street, W 1, all members of the medical profession will be welcome. During November the London Lock Hospital will hold a course in venereal disease, consisting of instruction in the out patients' department and lectures. At the Chelsea Hospital for Women there will be a three weeks' course in gynaecology, from November 2nd to 21st, and from November 3rd to 28th Dr Porter Phillips and Dr Thomas Beaton will give lecture demonstrations twice weekly on psychological medicine at the Bethlehem Royal Hospital. There will be a course in diseases of the chest, heart, and lungs at the Victoria Park Hospital from November 9th to 21st. The Royal Waterloo Hospital will hold a course from November 23rd to December 12th, covering all sides of the diseases of women and children. A late afternoon course (4 30 to 6) will be held by the London Temperance Hospital from November 23rd to December 4th for the benefit of general practitioners. Copies of each syllabus and of the general programme may be obtained from the Secretary, 1, Wimpole Street, W 1.

At the meeting of the Royal Microscopical Society on Wednesday last, among the papers communicated was one by Dr Helen Ingleby, formerly demonstrator of pathology in St George's Hospital, now acting professor of pathology in the Women's Medical College of Pennsylvania, on "the termination of the podic (perivascular foot) of fibrous neuroglia cells". A meeting of the section of industrial applications of the microscope is to be held at 20, Hanover Square, W 1, on Wednesday next, October 28th, at 7.30 p.m., when a contribution will be made by Mr J. I. Strachan on the microscopical structure of paper making fabric in relation to their manufacturing properties.

DR BABINSKI, the well known Parisian neurologist, has been nominated honorary professor of the University of Vilna. The diploma was recently conferred upon him in Paris by Professor Wladyslaw of Vilna.

THE King has appointed Dr Henry A. A. Nicholls, O.M.G., to be an unofficial member of the executive council of the Presidency of Dominica.

THE Minister of Health, the Right Hon. Neville Chamberlain, M.P., has appointed Mr P. N. R. Butcher to be his assistant private secretary.

A MEMORIAL tablet erected outside the main entrance of the Ladywell Sanatorium to the memory of the late Dr J. W. Mullen, for forty-two years superintendent of the institution, was unveiled by the Mayor of Salford on October 14th.

THE July issue of the *Kenya Medical Journal* contains the third and last part of a contribution on the biology of sleeping sickness by Dr G. D. Hale Carpenter, senior medical officer in charge of sleeping sickness, Uganda, and a full review of the report of the East Africa Commission. The journal is published monthly for the proprietors by the "East African Standard," Ltd., at 2s. This is No. 4 of volume II of the new series.

A BUST of Professor Poncet, well known for his work on tuberculosis, has recently been unveiled at the University of Lyons.

AN international children's exhibition will be held at Antwerp from October 27th to November 22nd.

THE Leeuwenhoek medal was presented to Professor d'Herelle, the discoverer of the bacteriophage, at a special meeting of the Dutch Royal Academy of Sciences on September 26th.

THE first Rumanian Congress of Obstetrics, Gynecology, and Urology will be held at Bucharest, under the presidency of Professor N. Gheorghiu, from October 25th to 27th, when the following subjects will be discussed: genital cancer, prophylaxis of puerperal infection, sterility following venereal diseases, clinical forms and treatment of extragenital tumours, Ambrud's constant, and the pyelonephritis of pregnancy. Further information can be obtained from Institutul Maternitatei, Spitalul Filantropia, B. Dn. Mihail Ghica 4, Bucarest.

THE American Medical Association has decided to publish a further periodical journal entitled *Archives of Pathology and Laboratory Medicine*. The first number will appear in January.

THE fund for extending the Stockton-on-Tees Hospital has received gifts of £10,000 from Sir John Roper, Bt., and £1,000 each from Sir Frank Brown, Sir John Harrison, and Mr T. Mellanby.

Earned Income and Annuity

"E. H." states that the relief in respect of earned income on his partner's share of the firm's assessment has been restricted because he pays an annuity to his mother out of that share.

* * This is apparently correct assuming that the annuity is not a voluntary one and that the partner is not possessed of "investment income" available for payment of the annuity. The statutory provision is Section 17 of the Finance Act, 1918, which states that "the claimant shall not be entitled to relief in respect of any income the tax on which he is entitled to deduct out of any payment he is liable to make."

The equity of the matter is that there are really two incomes—one which is earned and retained and another which is earned but handed over by legal obligation as an annuity. The payer is entitled to deduct tax from the annuity and therefore should be left in the position of having ultimately paid tax only on the retained portion of his earnings and on that portion he receives the allowance. To the annuitant the annuity represents "investment income" and she is not entitled to the earned income allowance in respect thereof. It may be added that if the annuitant's total income does not exceed £500 and she was 65 years of age on April 5th 1925 she can claim repayment in respect of an allowance under Section 15 of the Finance Act, 1925 equivalent to the earned income allowance.

LETTERS, NOTES, ETC.

PICTIC ACID COUNTS IN STAIN FOR TUBERCLE BACILLI

DR J. BARCROFT AND P. F. SOY (London) writes: In recording the results of the work of K. A. Jensen, and of Bender, in counterstaining preparations of tubercle bacilli with picric acid (*BRITISH MEDICAL JOURNAL*, October 10th, *Epitome*, para. 337), it is suggested that Bender's method in this method in 1921. I have used this method since November, 1920. It was first published by Carl Spengler in the *Deutsche medizinische Wochenschrift* No. 9 of 1907. It now appears on page 380 of his *Tuberkulose und Syphilis*, published at Dares Platz in 1911 and sold by Heintz and Roussel of that town. This method should really be much more efficient than even Jensen's represents it to be provided it is used in conjunction with a microscope having great depth of focus such as Davidson's 'saphia microscope' because sputum specimens so stained show the bacilli with clearness when the layer of sputum is about six times as thick as would be desirable with the Ziehl-Neelsen stain and consequently where the bacilli are few, it should be possible to find one in about a sixth of the time occupied in searching over the same area of a preparation counterstained blue.

HOMOEOPATHY BY A HOMOEOPATHIST

DR T. MILLER NEATBY (London S.W.) writes: I cannot complain of the tone of cheerful banter in which you deal with my booklet, especially as I should probably in your place have adopted the same tone, but I think I have a right to complain of the following sentence taken from your notice: "Arsenic cures syphilis because one of the most marked features of arsenical poisoning is a chronic skin eruption." If you will take the trouble to look through my booklet you will nowhere find that statement either overt or implicit.

* * The reviewer writes: Dr Neatby says that nowhere in his book is it implicit that arsenic cures syphilis because one of the most marked features of arsenical poisoning is a chronic skin eruption. Surely this is implicit in the doctrine of homoeopathy. In his book Dr Neatby observes that 'arsenic is very valuable for certain chronic skin diseases' and goes on to state that in an epidemic of beer poisoning 'one of the most marked features of that arsenical poisoning was a chronic skin eruption.' Later on Dr Neatby asserts that arsenic is undoubtedly homoeopathic to many severe cases of syphilis. From what had gone before it seemed natural to suppose that the author had in mind the chronic skin affections which form one of the most marked features of syphilis.

REFRIGATOID ARTHRITIS: ITS SEPTIC ORIGIN

MAJOR GENERAL SIR PATRICK HEHR, I.M.S. (ret.) K.C.I.E. C.B., C.M.G. writes: May I be allowed to add a note to the exceedingly interesting paper that was read and discussed on it that took place on the treatment of rheumatoid arthritis at this year's Annual Meeting of the Association published in the *JOURNAL* of October 10th. It was unanimously considered that the infective or microbic factor is the predominating agency through which rheumatoid arthritis is brought about. I have for over a quarter of a century been convinced that this is so. One of the commonest infective foci is that of the gums either in the form of pyorrhoea alveolaris or gingivitis, septic teeth being another. Pyorrhoea alveolaris was mentioned at the meeting, no harm is done in reiterating that it plays a part in a large number of cases of the disease under reference, it is very chronic and very difficult to eradicate. Often the pyorrhoea only ceases when all the patient's teeth have fallen out or been extracted. The shedding of the teeth may take many years, during the whole of which time the victim is absorbing toxins from the infective focus. When I was in practice, for all conditions

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *BRITISH MEDICAL JOURNAL* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *BRITISH MEDICAL JOURNAL* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *JOURNAL* should be addressed to the Financial Secretary and Business Manager.

SIR MAURICE CRAIG, C.B.E., M.D., F.R.C.P., President

DISCUSSION ON TREATMENT OF INSOMNIA

OPENING PAPER

BY

ROBERT HUTCHISON, M.D. EDIN., F.R.C.P.,
Physician, London Hospital and Hospital for Sick Children,
Great Ormond Street

For purposes of treatment cases of insomnia may be divided into two groups (1) the secondary, (2) the primary.

In the secondary group the insomnia is the result of some physical discomfort, such as pain, fever, dyspnoea, cough, flatulence, toxæmia, and so forth. The primary or intrinsic cases, on the other hand, either arise from some psychical discomfort (worry, anxiety states, etc.), or they are originally secondary cases in which the physical cause having disappeared, the insomnia has persisted largely as the result of auto-suggestion. The secondary cases are of most interest to the general physician, the primary to the psycho-neurologist and the alienist.

SECONDARY INSOMNIA

The treatment of the secondary cases is primarily that of the associated disease. One tries to relieve pain by local applications, fever by hydrotherapeutic measures and antipyretics, cough by expectorants, and so on. In many cases, however, these measures fail to give sleep, and the question of a suitable hypnotic will arise. It will be generally agreed, I think, that there is no objection to the use of hypnotics in these cases from the fear of establishing a habit, seeing that we are usually dealing with a disease of short duration in which the promotion of sleep, if necessary by artificial means, is essential for the maintenance of the patient's strength and powers of resistance. The choice of a suitable hypnotic, however, is not always easy, and is a matter which we may profitably discuss.

When the insomnia is due to pain I think we shall all agree that, unless the disease is likely to be of short duration, we should try analgesic drugs first before having recourse to morphine. Aspirin or pyramidon may serve the purpose or we may use one of the newer drugs such as dialyretin or veramon. I have had very little experience of the former and almost none of the latter, but I believe them to be very useful in many cases of insomnia due to pain and discomfort, and it will be interesting to hear the opinions of any who have used them more extensively. In many cases, however, we are compelled to fall back upon morphine as the only effective agent for abolishing the pain, and I would suggest for purposes of discussion that substitutes for morphine, such as heroin or one of the preparations of the "total alkaloids" (omnopon, alopon, etc.) have no real advantages.

When dyspnoea produces insomnia the hypnotic selected will depend on the cause of the dyspnoea. In cardiac cases there is no drug to equal morphine, which often exerts an almost magical influence, but in dyspnoea of pulmonary origin associated with much emphysema—as in bronchitis, for example—it is usually contraindicated. In such circumstances opium may sometimes be safely given by the mouth as in the form of Dover's powder, strychnine and oxygen inhalations are useful adjuncts. When these measures fail the choice of another hypnotic is often a difficult one, but paraldehyde, either by the mouth or the rectum, is perhaps the most suitable. I would suggest, however, that there are cases of this kind in which the induction of

deep sleep by any means is unsafe, as it causes the retention of secretion in the air passages. Pneumonia is a disease in which insomnia often results from a combination of several physical factors—pain, fever, cough, dyspnoea, and toxæmia—all playing a part in it—and the problem of how to promote sleep often taxes the resources of the physician to the utmost. In the early stages—say before the fifth day—morphine is much the most effective agent for the purpose, and I think it wise to use it unhesitatingly at this period in order that the patient may have some sleep "in hand." After the fifth day it is rarely safe to use morphine, and some other hypnotic must be chosen. Opinions differ as to which is the most suitable. Chloral, which is one of the most effective, is often said to be dangerous because of its depressing effect upon the circulation, but I would suggest that this danger is exaggerated. Paraldehyde is the safest, but is apt to be uncertain in its action. I believe that it is commonly given in too small doses, and that 2 drachms at least are required to ensure an effect. If the taste is objected to, it may be given in larger doses by the rectum. I have been disappointed with the action of the veronal group in pneumonia. For the allaying of cough which is causing insomnia codeine is probably the best remedy.

In the sleeplessness of uræmia, whether associated with dyspnoea or not, I am of opinion that morphine is most effective, and that the common prejudice against its use in renal cases is unjustified. If there is much restlessness and delirium as well as insomnia in uræmia I have sometimes had very good results from the hypodermic injection of hyoscyne (gr. 1/100).

PRIMARY INSOMNIA

It is well at the outset to make sure that the case is really one of primary or intrinsic insomnia, and not one of secondary insomnia in which some physical discomfort has been overlooked. Dyspepsia and constipation may cause sleeplessness although the patient is hardly aware of their existence. Flatulence, either in the stomach or colon, seems specially prone to act in this way, probably by interfering with the heart and so disturbing the cerebral circulation. It may therefore be worth while, when no psychical cause for the insomnia is evident, to try the effect of an alkaline carminative draught at bedtime. I believe that senile insomnia is often due in part to flatulence, and that a glass of hot grog as a "night-cap," which is admittedly successful in combating it, exercises its effects by expelling wind as much as by improving the circulation.

If the patient's insomnia is really of the primary variety our first duty must be to inquire into causes of mental discomfort, which will usually take the form of some anxiety state. The elucidation of this, however, and still more its removal, may take time, and meanwhile the patient clamours for sleep. In these circumstances I believe that our first task should be to try to get the patient to adopt the right mental attitude to the symptom. There is no use in telling him that it does not matter whether he sleeps or not. He knows better than that. He has probably, however, been exaggerating in his own mind the results of not sleeping, and one may certainly explain to him that there is no fear of his either dying of insomnia or of going mad as a result of it—both of which ideas have probably been preying on his mind. One may also point out that health can be maintained on a much smaller allowance of sleep than most people habitually take, and that complete rest and muscular relaxation are to a large extent a substitute for it. If the patient can only be got to take up this mental attitude to his trouble it is a big step towards curing the insomnia, for the latter is often being kept up through auto-suggestion, the patient does not sleep because he goes to bed dreading that he will not. If he can be got to snap his fingers at the insomnia it will often disappear.

At an early stage in the management of all severe cases the question of the relative advantages of homo or institutional treatment will arise, and this is a point which we may profitably discuss. Unless the insomnia has resulted from mental overwork (and I believe this, in the absence of coexisting worry, to be a rare cause), in which case going

off for a holiday may effect a rapid cure, I believe it to be best to cure the insomnia, if possible, in the environment in which it arose, though I am aware of the advantages of institutional treatment in cases requiring prolonged psychotherapeutic treatment, and, of course, in all the psychoses.

Meanwhile, if the patient is to be treated at home, and especially without drugs, he must be taught to manage his insomnia pending its cure. He should have a bedroom to himself, and should be provided with food to take during the night, and some not too exciting mental pabulum as well (the novels of Anthony Trollope are very suitable), while the puzzles and patience may also help to fill up the wakeful hours. By day he must cut down his activities, both mental and physical, to the minimum, he must keep warm and feed well, but eschew cerebral excitants such as tea, coffee, and tobacco in excess.

Last we come to the use of drugs. I believe it to be prudent to say that hypnotics should only be used in insomnia as a last resort. I would suggest that the fear of establishing a "habit" is a bugbear, and that the possibility of the insomnia becoming a habit is a much more real danger. I believe, in short, that there are few cases of bad insomnia in which the prescription of a hypnotic is not required at some stage or other. The removal of an anxiety state or the resolution of a conflict may be the aim, and meanwhile, especially if the insomnia is becoming absolute, and in most of the psychoses, artificial sleep must be induced. We have now a large choice of drugs for this purpose, ranging in potency from the bromides to luminal, but as we cannot afford to fail without making the patient worse than ever it is wise to begin with a hypnotic, or a dose of it, which is probably rather more powerful than is really necessary. The bromides are therefore only indicated in the mildest cases, but the urea-bromine compounds (bromural and adalin) are better. I have used them with success in many of the less severe cases, and they have the merit of being safe and of producing no unpleasant after-effects. Of the more potent drugs the veronal group is on the whole, the best, and medinal (sodium-veronal) in 7½-grain doses will meet most indications. Paraldehyde has the disadvantage that it advertises itself too openly, but chloral has probably fallen too much into disuse. It has the drawback of irritating the stomach, but that can be overcome by suitable methods of administration, and in a cardinal degeneration I believe it is otherwise quite safe although it is perhaps wise to avoid it in cases of myocardial degeneration. I believe it is otherwise quite safe. It has been used, of course, for suicidal purposes, and in a few cases a "chloral habit" has been set up, but these are risks which we must take. Chloralamide I regard as too uncertain in its time of action to be relied upon. Of the other hypnotics, trional, from its somewhat delayed action, is specially indicated in those cases in which the patient is awake only in the latter part of the night (so-called inter-nocturnal insomnia). Sulphonal, though largely used in asylums, is, I consider, inferior to trional. Luminal is unnecessarily powerful for use unless in exceptional circumstances, and morphine should never be administered in primary insomnia outside a mental hospital. The question of how best to wean a patient from his hypnotic once it has done its work is a difficult one, and part of the discussion might properly be directed to it.

GENERAL DISCUSSION

Dr HARRY CAMPBELL (London) defined insomnia as "the inability, given favourable external conditions, to enjoy a sufficiency of normal sleep." Sleeplessness arising from unfavourable external conditions was not insomnia. By a sufficiency of sleep he meant an amount which was normal for the individual, and thus depended upon age, sex, and individual constitution. Normal or physiological sleep was to be distinguished from morbid sleep, (b) was undisturbed by harassing dreams, and (c) from which the sleeper awoke refreshed. Insomnia, according to the above definition implied, not merely the inability to enjoy normal, physiological sleep, but the conditions were often combined with those who did not sleep long enough generally slept only when they did sleep. Others who slept long enough, perhaps

too long, did not enjoy sound refreshing sleep, and such might be said to suffer from a species of insomnia.

The object of the physician was to secure for his patient a sufficiency of normal sleep. All persons in the enjoyment of sound physical and mental health slept well under moderately favourable conditions, from which it followed that the supreme aim of the physician in treating sufferers from insomnia should be to raise the patient's health to the highest possible level. It was more particularly in chronic insomnia that this injunction should be kept in mind. In these cases there was a temptation to treat the patient in a "finicking" way, forgetful of the grand truth that a healthy person was a good sleeper.

Correction of Intrinsic Factors

In treating insomnia it was necessary to institute a minute search for causes, intrinsic and extrinsic. That physician would be most successful in treating the condition who was prepared to devote infinite care to matters of detail. Disturbing intrinsic factors might be either mental or physical. As regards the intrinsic mental factors, a careful search must be made for sources of psychic irritation, such as mental conflicts, apprehensions, worry. The patient, if present, called for psychological treatment. The patient should retire to rest in a tranquil state of mind, with the belief that he was really going to sleep, the contrary belief was a potent cause of insomnia. He should also endeavour to harbour pleasant thoughts. It was useless for the sleepless patient to try to go to sleep, the attempt tended to irritate rather than to soothe, an attitude of indifference was more likely to be followed by sleep. Belief operated by suggestion, whether it was spontaneous or had been implanted by the physician. Dr Campbell had known a lady to take a placebo pill every night, with rare exceptions, for years, under the impression that it contained a hypnotic, she declared that she could not sleep without one. The patient should avoid close mental work in the evening. If that was not possible he should go for half an hour's stroll before going to bed, so long as it did not exert, companion. Reading in bed, and there were those who habitually often promoted sleep, and there were those who habitually read on getting into bed until drowsiness compelled them to put out the light. A spell of wakefulness during the night might often be relieved by turning on the light and indulging in reading for a short time. Fear of the dark was a not infrequent cause of sleeplessness in children. On the physical side, the chief aim should be to raise the patient's health to the highest possible level. If only he could be rendered well both mentally and bodily, in insomnia, in the absence of environmental disturbance, would certainly disappear. It was all the more necessary to keep this truth in mind when, as so often happened, in sufferers from inveterate insomnia there were obvious signs of disease. Any disturbance of function that might be present should, as far as possible, be corrected and an endeavour be made to promote health. Unfortunately the of life calculated to get the sufferer to accept a mode of life was not always able to arrange his life entirely. One would wish, but it was seldom that he could not be given sound practicable advice. A careful inquiry should be made into his past history and present conditions, his daily routine, the arrangement of his meals, the hours and conditions of his work. When the blood pressure was high steps should be taken to reduce it by means of the diet, or even salines, and, if necessary, by curtailing the diet, or even by recourse to bleeding. In these cases a tabloid of nitrates, allowed to dissolve in the mouth the last thing at night, might be of service. Sources of intrinsic peripheral irritation—pain, cough, nasal obstruction, dyspepsia, frequent micturition, pruritus, cold feet, gastro-intestinal disturbance—should be sought for and treated on general principles. Cold feet might be followed by the hot mustard foot-bath, by the use of night socks, by vigorous friction, and by the removal of such disturbing factors as flatulence and hunger-pain. Patients liable to the latter should take some food, such as warm milk or soup, just before going to bed, or on waking up in the

Dr. H. Deane (Portsmouth) said that Dr. Hutchinson had pointed out that cases of insomnia might be divided for therapeutic purposes into two groups: (1) secondary, where the insomnia was a reaction to physical pain, illness, or discomfort; (2) primary, where the insomnia was an inherent symptom of a disease, in the same way (for instance) as was a cough in bronchitis. He had pointed out, furthermore, that it was the primary form of insomnia which was the more interesting to the psychiatrist, and it was to this form that Dr. Deane's remarks would be directed, and more particularly to the insomnia associated with severe psychotic conditions. Sleeplessness accompanied by psychomotor unrest, was a common symptom in most of the acute psychoses—manic depressive insanity, confusional and exhaustion psychoses, alcoholic delirium, general paralysis, dementia praecox etc. and treatment had naturally to be directed to this condition or collapse was liable to be due to this condition or collapse stupefied the patients, and which had been described as "chemical restraint," was steadily growing into disfavor. With increased knowledge of the possibilities of treatment, it had been found that recovery was favoured when the symptoms manifested in the acute psychoses were regarded as the outward expression of a morbid state of the organism. Endeavours were therefore made to assist nature to bring about a cure by careful nursing and medical treatment similar in kind to that given in acute medical illnesses, and aiming of course with the biological changes present. It was frequently found that the organism in these cases was unable to cope with itself, it did not digest food properly, metabolic processes were disordered so that waste products were not eliminated, a sufficient rate and wasting rapidly occurred. Frequent feeding with liquid diet on account of its ease of administration and also its value in diminishing the burden on the alimentary system was prescribed. The body was bathed frequently to promote skin elimination, attention was given to the bowels and alkalis administered with a view to neutralizing acidity. Direct attempts were made to promote sleep by means of sponging hot-packs or, if the condition permitted prolonged baths. Such measures did not always suffice to produce sufficient sleep and naturally hypnotics were often necessary. These were used as sparingly as possible however and in conjunction with such methods as had been described they undoubtedly had considerable therapeutic value. It should be mentioned that Klasi and other psychiatrists had utilized a drug, called somnifen to produce a prolonged "twilight sleep" for therapeutic purposes in the psychoses. The sleep which had been maintained for six or seven days resembled lethargic encephalitis—the patients could be aroused to take nourishment or pass excreta and dropped off again when quiet. Favourable results were reported, but the treatment seemed rather drastic and was not free from danger. One could

Correction of Extrinsic Factors

The bedroom should be dark, quiet, and well ventilated. A spring bed was best, and it should be placed away from the wall. The mattress should not be uncomfortable and hard, one who was accustomed to a soft mattress often found it difficult to sleep on a hard one. The bedclothes should be no more than sufficient to keep the body comfortably warm. The height of the pillow deserved consideration. I wish what height was most conducive to sleep was mainly a matter of habit. When the blood pressure was not normal and the patient was otherwise healthy a low pillow was best, but in cases of high blood pressure the pillow should be high. One was apt to forget that the influence of the horizontal posture in augmenting intracranial pressure was considerable and might play a small part in determining cerebral haemorrhage. The mattress and bedding should be thorough and clean. This was especially necessary in the case of those who were liable to cold feet and attacks of shivering such as might occur in women at the climacteric. It was much easier to keep warm in a well aired than in a damp bed, and it should not be forgotten that in damp weather the bedding was capable of absorbing much moisture. It might then be advisable to give the entire bedding an occasional airing by the fire. In the case of cold subjects the bed in cold weather should be well warmed in means of a hot water bottle. There was no advantage in getting into a cold bed, a warm bed was a luxury which might always be safely indulged in when the weather was cold. Patients usually preferred to sleep on the right side, doubtless because the ponderous liver was situated on this side but it was well to be able to sleep on either side indifferently and not become too great a slave to habit. Some were so wedded to habit that they could not sleep in a strange bed or bedroom. The more one emancipated oneself from bondage of this kind the better. The bad sleeper should sleep in a bed by himself. The bad sleeper sleep with the mother, but in a separate cot, and should not be fed during the night. The nursing should not be a prospect of an undisturbed night's rest. Children over 2 years should not sleep in a room occupied by adults and should occupy separate beds. Exercise in the open air such as was provided by golf, was conducive to sleep. In cases of intractable sleeplessness it was sometimes a good plan for the sufferer to get up early and occupy himself out of doors. The green grocer who had to go to market in the small hours of the morning and was busily occupied all day in his own shop was little likely to suffer from sleeplessness, and the same was true of the peasant who rose with the sun and worked in the fields most of the day. A warm bath at bedtime sometimes, promoted sleep. The addition of a little mustard might enhance its effect. A hot mustard foot-bath was sometimes helpful, especially in cases with a tendency to cold feet. The Turkish bath might also be of use. In moderate cases the wet pack might be tried. This method was formerly much used in hospitals until it was injudiciously prohibited as unnecessarily severe. The plan of sleeping in a wet nightgown had been advocated. One of Campbell's patients adopted this plan for several years. A bout of wakefulness at night might sometimes be terminated by getting out of bed and dousing the face and neck with cold water, vigorously brushing the hair and arms, than the ordinary night gear. As regards climate, it was well known that some resorts were much more conducive to sleep than others. High altitudes were generally unsuitable for bad sleepers. For most patients the lower altitudes and a warm climate were preferable. In the home of a climate for a sleepless patient the latter's personal experience was however the best, indeed the only safe guide. The factor of suggestion had also to be reckoned with. If a person got it into his head that he was not going to sleep well in a certain place his expectation was likely to be realized. Some patients lay awake until towards the morning, when they fell into a sound

not but feel that such treatment was analogous to the treatment of a fever by forcing the temperature to normal with powerful antipyretics. A treatment must be judged by its results, however, and Klags had evidently found his methods of value where all else had failed. Dr Devine did not propose to discuss further the means of combating insomnia in severe psychotic cases. It would appear more profitable to suggest some directions in which the treatment of insomnia in the psychoses enabled them to understand and treat this condition in the milder cases found in general practice. In the first place it would be observed that they did not in the psychoses aim chiefly at treating the insomnia itself, but rather the morbid processes in the organism responsible for its occurrence. The point Dr Devine wished to emphasize was that the insomnia was essentially a secondary insomnia in the sense that it was a reaction to a morbid and sensitive state of the organism. The insomnia, it was true, was not here due to the pain or discomfort associated with a clear cut physical disease, rather was it due to a vague, ill defined, and imperfectly understood state of the organism as a whole, which was registered in consciousness as excitement, depression, confusion, and the uprush of morbid ideas and images, and it was the excessive preoccupation with these experiences which prevented the patient from sleeping. He would therefore make the following generalization, that in treating a case of insomnia they should always seek for the underlying and persistent stimulus which was responsible for keeping the organism awake. This stimulus might be an easily localized pain or discomfort, or an intangible alteration in the organism which was felt, not as a localized pain, but as an alteration in the emotional or affective state (depression, elation, anxiety or fear, etc.), but in either case they aimed at relieving the hidden cause of the sleeplessness. Dr Devine was anxious that this formulation should not be regarded as an instance of academic theorizing in which psychiatrists were perhaps prone to indulge. He thought there was a definite practical value in regarding all cases of insomnia as the outward expression of a malfunctioning or pain-stricken organism, it certainly ensured their searching for objective evidence of biological changes in the organism. They might regard changes in the emotional life as an exquisitely delicate register of the state of the organism, and for this it would seem to be essential in all cases of primary insomnia to make careful observations on the emotional life of its subjects. This suggestion was made because he felt it to be highly probable that many such cases were minor forms of psychosis such as were met with in severe form in mental hospitals. Insomnia was a frequent prodromal symptom of the psychoses, and it was obvious that if they recognized the condition as being due to the depressed or excited stage of cyclothymia, a mild exhaustion psychosis or presenile depression, or possibly an early case of general paralysis, their treatment could be applied with much greater confidence and skill, as they felt that they understood what was wrong and the probable outcome of the case. Probably many of the cases of suicide recorded in the papers, in which sleeplessness was so often described as the symptom which was most noticeable to the relatives, were really instances of depressive psychoses which would have yielded to treatment in a clinic or hospital. Unfortunately, however, there was practically no hospital provision for the treatment of these milder psychotic cases. Dr Devine did not wish to suggest that the majority of cases of insomnia were due to psychotic conditions. Many were due to anxiety states which indicated the existence of what Kemp had well named "autonomic cravings" which were inhibited from free expression. Such cases yielded to psychotherapy, which relieved the tension of the organism and enabled the individual to adjust with confidence and freedom to the life he was called upon to live. In such cases, of course, a full exploration of the patient's domestic, business, social, and sexual life was essential, and they certainly could not ignore the last because a great deal of anxiety and insomnia must be due to inadequate functioning in the sexual sphere in view of the unbiological modes of living which modern life imposed on so many members of the community.

Dr C P Symonds (London) stated that, as they knew so little of the physiology of sleep, any explanation of insomnia upon a physiological basis must needs be somewhat speculative. Nevertheless, he hoped a brief physiological digression as an introduction to some remarks upon the practical treatment of insomnia would be excused. The essential feature of sleep was loss of consciousness, consciousness was presumably a function of the cerebral cortex, sleep therefore implied temporary cessation of function in these cells. The activity of these cortical cells depended upon stimuli which were constantly reaching them from other points of the nervous system. When they were refreshed after a period of rest these cells needed comparatively little stimulation to excite them to activity, when they were normally fatigued after a day's work the stimulus required was greater. Somewhere at the base of the brain he assumed that there was a mechanism which could inhibit the flow of impulses towards the cortex, as it were a lock gate partially obstructing the stream. In the ordinary way this sleep centre came into action at a regular interval once every twenty-four hours. Thus was a reflex process, and might therefore be facilitated or inhibited by a great variety of conditions which might differ in different individuals and were subject to alteration. Such were the ordinary bedtime habits. This schema provided at any rate a simple classification of the insomnias. Sleeplessness might be due to (1) An abnormal increase in the flow of stimuli so that the stream overflowed or forced open the lock gate, and the cortical cells, in spite of their fatigued state, were subject to a degree of stimulation which was sufficient to maintain them in a state of activity. Such increase in the stream of stimuli might be due to pain, discomfort, or anxiety. (2) The sleep centre itself might be out of order so that the lock gate did not close, and for this reason the cortical cells, though normally fatigued, were still subject to a stream of stimuli sufficient to keep them in a state of activity. These were the cases in which the habit of sleep was lost, often as a secondary result of prolonged insomnia from pain or anxiety. (3) The excitability of the cortical cells might be exalted as the result of imperfect oxygenation, toxæmia, or excessive fatigue, so that the normal minimal stream which always flowed beneath the lock gate after it was closed was sufficient to keep them in a state of activity.

The causes of insomnia due to an increase in the flow of stimuli to the cortex had, as regards its physical side, been ably dealt with by the opener of the discussion. On the psychological side it was the unpleasant emotions—*anxiety and fear*—which most readily prevented sleep. With Dr Hutchison's opinion as to the justifiable use of hypnotics in such cases pending the results of psychotherapy Dr Symonds was entirely in agreement. It should merely be borne in mind that all the hypnotic drugs were poisons and should therefore be used with judgement and common sense, and that every hypnotic—including paraldehyde—if used continuously was apt to create a habit. The principles guiding the use of hypnotics in cases of neurosis should be, first, not to continue with drugs for more than a week or so without openly or covertly reducing the dose and observing the result, secondly, never to exhibit the same hypnotic for more than three nights in succession. An alternation of medinal, chloral plus bromide, and paraldehyde allowed plenty of scope. Reference had already been made to the anxiety about sleep which was such a common development in anxiety neuroses. It was clear that so long as a man was worrying over the question whether he would get to sleep or not, and, if so, whether he would get a sufficient sleep, he was not likely to attain his object. Dr Symonds had found it a good plan in such cases to give a dose of paraldehyde (53 to 54). This resulted as a rule in a sound sleep. The patient was instructed to take a holiday next day which should include an and exercise. He was further instructed on the three succeeding nights to have the same dose of paraldehyde poured out by his bedside, and to take it without hesitation if he could not sleep without. Being thus assured in any case of a good night, he would often need no further dose of hypnotic, but might be allowed to have a single dose in his possession to take at need. The little bottle thus

acted as a charm which kept the spectre of insomnia away from an ease in which insomnia had persisted longer than a week or two the sleep reflex itself was apt to be disturbed. The conditions which in the past had favoured the closing of the lock gate lost their effect, and might even from continued association with insomnia inhibit rather than facilitate the onset of sleep. Quiet and darkness, the ordinary bedtime ritual of undressing and washing, even the accustomed bedroom itself, instead of inviting sleep repelled it. Hence the value in any case of long standing insomnia of a change in the surroundings. At the outset of treatment it was often a good thing to move the patient into a new bedroom, and to prescribe a new routine in which physical and psychological factors might be combined to facilitate new habits of sleepiness. A habit which was valuable in some cases was that of muscular relaxation. It was possible by an effort of will to relax the muscles of a limb so that it lay inert, it was possible, but not easy, as anyone might prove by trying for himself to allow his arm to remain passive while it was moved by another. With training the ability to relax might be developed so that a patient might learn to relax all his limbs in turn and finally together. This exercise in relaxation was especially valuable in people who were kept awake by the "fidgets." Fidgeting which had originated from pain or worry might be perpetuated as a habit—in the same way as a tie. In such cases muscular relaxation, which might be practised at other times during the day, should be included in the bedtime ritual.

As to allowing patients who were suffering from insomnia to read or play patience in order to pass the time, Dr Symonds was not convinced of the wisdom of this plan. One would rather suspect that it would tend towards a habit of wakefulness, for the patient who woke during the night should, he considered, be discouraged even from turning on the light to see the time. He should be encouraged to think of relaxation and sleep, to repeat familiar verses to himself, or even to count the classical sheep as they passed through the imaginary gate. Some persons had a happy knack of day-dreaming which stood them in good stead on these occasions and would drift off to sleep happy the while they landed prodigious trout, hit tremendous dives, or sailed easily up gradients of 1 in 5 at the wheel of a Rolls-Royce. As aids to sleep such habits should be encouraged.

Whether or not patients suffering from insomnia should be treated at home was a question upon which no general rule could be laid down. In the cases of emotional origin it was often necessary to have the patient at first away from his own home for the sake of the emotional rest which such a change provided. This applied especially to women, who found it difficult to rest in their own homes.

Finally, there were the cases of insomnia in which the excitability of the cortical cells was exalted as the result of anaemia or intoxication. Dr Symonds would suggest that the sleeplessness of pneumonia and other conditions in which there was cyanosis was partly due to this cause. At one time during the war, when he had under his care a number of men suffering from gas poisoning, he was impressed by the hypnotic effect of oxygen administered continuously through the nasal catheter. Subsequently he used the same plan in the treatment of the influenzal pneumonias with cyanosis. In certain cases the continuous oxygen would bring sleep even when morphine failed. Included in this group was also the insomnia which might result from excessive mental fatigue. Here, no doubt, as the result of over-exhaustion, some biochemical change occurred in the cortical cells which increased their excitability. When the worker sought repose he found himself kept awake by the tumult of his own thoughts, and was at the same time susceptible to the least external stimulus. This was a common form of occasional sleeplessness in intellectual workers. It might easily lead to a disturbance of the sleep habit. Therefore, as an occasional symptom it should be promptly treated. A whisky and soda or 5j of bromidia was usually a sufficient remedy, followed by a holiday week end if practicable. In this group of cases in which the insomnia was due to over-excitability of the cortex drugs were in essential part of the treatment, and as a rule large doses were needed.

Dr Symonds agreed with the opening of the discussion as to the value of paraldehyde, but believed that there was some truth in the tradition prevalent among nurses that paraldehyde might cause an increase of restlessness and excitability. When this occurred it meant, as a rule, that the dose given was too small. If an hour after a 2-drachm dose of paraldehyde the patient appeared to be more restless than before, a further dose of 1 drachm would sometimes induce sleep within a quarter of an hour.

Dr E. I. SERRICES (Ruthin Castle) considered that in the case of the overworked business man suffering from insomnia the best remedy was for him to get out of doors for one or two hours every day. This procedure was more important even than rest, and was far better than the taking of hypnotics. In any case he was not in favour of giving a continuous hypnotic. Nervous and excitable patients should take a short rest after the midday meal, this was often helpful, and did not in the least interfere with the night's sleep. An important factor was the patient's mental attitude towards wakefulness. Reading in bed might often assist the coming of sleep, but the literature had to be chosen with care, and the period of reading should be limited to ten to fifteen minutes. Novels were useless owing to the tendency to peruse them to a finish, the book of Job, Evelyn's *Diary*, and Carlyle's works were more suitable.

Dr D. STONE (Northampton) said that the posture adopted by patients in bed was worthy of consideration. They should lie on the right side, as in this position it was easier for the stomach to empty. The actual amount of sleep necessary varied with the individual, some required more than others. With advancing years less sleep was usually needed. He was not in favour of going to bed on an empty stomach, and considered a moderate meal advisable. From thirty years' experience in general practice he had found that paraldehyde was the best hypnotic for ordinary use, he preferred doses of 1 drachm, as 2 drachms rendered the patient's breath offensive for thirty-six hours. Bromium and veramon also were often successful. For patients with hyperacidity he advised 20 to 30 grains of sodium bicarbonate with a carminative. For those who were assisted to sleep by reading he recommended Young's *Half-hours with the Best Authors* as the most suitable book.

Dr JOHNSON SMYTH (Bournemouth) stated that of his last hundred patients ninety were over 50 years of age, and 70 per cent of these had insomnia—hence his interest in the symptom. He classified cases of insomnia into three groups. Group 1, the cases met with chiefly in asylums, in which the cerebral cortex was in process of destruction owing to advanced brain disease. Such cases were hopeless. Group 2, those occurring in the earlier periods of life, where more often than not the cause was a solitary one—pain or a psychic disturbance—a love affair, a debt, etc. With the removal of the pain or the settlement of the debt the case recovered. Group 3, cases in the later periods of life, in which, more often than not, the factors behind the symptoms were multiple. Pain was frequently present in association with psychic factors, and irregularities of blood pressure were also nearly always found. Cases now and then might reveal neither pain nor psychic disturbance, and to all intents and purposes the patient was in good bodily condition. The solution of the problem in such cases was surely to be found in a cerebral disturbance brought about by the afferent fibres of the vegetative nervous system—it might be from some obscure pelvic, abdominal, or chest ailment not discovered—and which had not revealed its presence by actual pain, yet the messages proceeded upwards unknown to the individual, but resulted in sleeplessness. Dr Johnson Smyth advocated change of air and scene for cases of severe insomnia. He recommended bromine or bromides only where great restlessness was present, but massage given in silence at 9 p.m., followed by medical at 10.30, combined with the cultivation of a contented mind, gave the best results. He recommended light literature at bedtime—such as *Robinson Crusoe*, *Aesop's Fables*, or a good translation of Iliad. The

greatest contribution of all to a contented mind was, he considered, to be found in the consolations of religion.

Dr W. A. Potts (Birmingham) drew attention, in the cases in which drug treatment was necessary, to the value of combining morphine and hyoscyne. The combination enabled a smaller and safer dose of each drug to be used. If there was any fear of harm resulting from the by-products of hyoscyne, this was diminished by giving at the same time a tumbler of water, preferably hot, which was in itself sometimes an effective hypnotic. In certain selected cases alcohol, in a sufficient dose, was valuable, but due regard must be paid to the possible dangers. Among simple drugs a dose of "blue pill" was often valuable, as might be expected from what they had heard of alimentary toxemia. As regards predisposing habits, tea, coffee, and tobacco were to be considered, they might be taken in too large quantities or too late in the day. Finally, Dr Potts desired to emphasize what Dr Devere had said, that on the psychological side it was ineffective work more often than overwork that caused the trouble. In many cases a few hints to the patient as to how he could be more effective were valuable.

Dr C. Montlock-Brown (Biauton) pleaded for further research into the physiology of sleep. She had found that outdoor exercise prior to retiring for the night was often helpful. Hypnotics should be given only as a last resort, and prescriptions for these drugs should, she considered, be invariably endorsed "Not to be repeated." Much might be done from the preventive standpoint by the correct upbringing of children and the avoidance of tea and alcohol.

Dr R. Mackenzie Wallis (London) referred to certain investigations he had carried out regarding the relative toxicity of hypnotics. In many cases of mental disorder it was necessary to administer hypnotics, and in some such cases he had investigated the effects of the drug on metabolism. The functional methods of diagnosis of hepatic and renal insufficiency were used for this purpose. The drugs used were sulphonal, veronal, and medinal (sodium-veronal). In practically all cases no evidence of a toxic action on the liver or kidneys could be found in spite of the administration of the hypnotic over several months. They were also rapidly excreted and there was no evidence of cumulative action. It was also possible for a normal individual to take these drugs during the day without the induction of sleep. In view of these observations, it was inadvisable to withhold hypnotics when other conditions warranted their administration.

Dr T. A. Ross (Penshurst) dealt with the influence of suggestion. The patient was often helped by anything the doctor himself believed in, and many drugs (for example, aspirin) might act purely by suggestion. All the so-called primary insomnias were really secondary, but the cause was less obvious than in the cases termed "secondary." It was necessary to ascertain what was at the bottom of the apparent primary cases. Dr Ross agreed that at times it was necessary to give hypnotics, although their administration certainly tended to inhibit the process of psychological investigation.

Dr Woods Hutchinson (California, U.S.A.) said that the great handicap in treating insomnia was that they had no idea of the physiological mechanism of sleep. Further, the symptom of insomnia depended upon the testimony of the patient, and as no individual could assert how long he slept the patient's statements were usually erroneous. On careful watching by a nurse, the patient being unaware, in many cases of alleged insomnia it had been shown that sleep was really quite good and sufficient. The best mental attitude to persuade the patient to adopt was an endeavour to forget his sleeplessness.

Dr R. Whittington (Hove) considered that the individual temperament of each patient was of great importance and had carefully to be studied, the same remedies that suited one person did not meet with success in another.

He would have liked to hear more of the treatment of insomnia by suggestion or hypnosis.

Dr H. Clouston Murray (London) said that he agreed in the main with Dr. Hutchinson's "robust realism." The bogey of habit formation dominated unduly then use of hypnotic drugs. He wished to emphasize the point that many cases of apparently "primary" insomnia were in reality secondary. The commonest group was that in which patients woke in the early morning for no apparent reason. On close investigation it was often found that they were, in fact, suffering from gastric fermentation of a degree which was not sufficient to cause acute discomfort, yet sufficient to determine pressure on the abdominal aorta and so interfere with that degree of cerebral ischaemia which they knew to be an essential condition of sleep. In this connexion he disapproved strongly of the usual procedure adopted by nurses—namely, the glass of hot milk. As a warm beverage it did its work and generally sent the patient to sleep, but as few adult patients could digest, when recumbent, half a pint of milk, fermentation followed, which in course of time woke the patient. If, on the other hand, a warm drink of a non-fermentable character were administered the results were likely to be more satisfactory. Dr Campbell had referred to cold feet as an "instigator" that militated against sleep. In point of fact this condition was more than an instigator, it revealed a state of circulatory disequilibrium involving inter-arterial vasculature to a degree that rendered sleep well-nigh impossible. The question of circulation was most important to bear in mind in studying insomnia. Dr Whittington had rightly emphasized the necessity for studying individual cases. Many of their disappointments were due to ignoring the vascular state of the patient. It was useless to expect the same remedies to produce the same results in patients with high and low blood pressures.

The President (Sir Maurice Craig) said that they were much indebted to Dr. Robert Hutchinson for the able way in which he had opened the discussion and for placing the subject before them in so general and yet so clear a way. This discussion had brought out very clearly how varied were the methods of treating insomnia. He agreed in the main with much that had been said. Like many others, he had been brought up to fear the use of hypnotics lest perchance by prescribing such he might set up a habit of drug-taking in his patient. Thirty years' experience had taught him the folly of such an attitude. He had learnt to fear the dangers of insomnia, which were real, and to appreciate that the danger of starting a habit was to a very large extent chimerical. As a profession they were apt to think in bromide, a drug infinitely more harmful than most hypnotics. Bromide in large doses was very damaging to the stomach, and it rapidly confused the mind without giving sleep. It was far safer to use diol or medinal or any other drug which was found effective. Sir Maurice had listened to Dr. Mackenzie Wallis's remarks with more than usual interest, and his findings bore out his clinical experience. He (Sir Maurice) had used sodium veronal very freely for a great number of years and had never seen any bad results. He found that the patient improved both mentally and physically and that the danger of habit was infinitesimal. Sleeplessness should be treated seriously from its earliest onset, and with some types of patient not to do this was to endanger his mental equilibrium. A further point of importance was, once a drug and the dose required to give good sleep were found, never to stop or change until the patient's health had been fully re-established for some time. To stop it for a night or two meant, in the majority of cases, that the effect was lost, and thus produced a psychological effect in a belief that sleep would never be restored. The early relief of sleeplessness was the safest course to avoid any drug habit, as the patient never lost his confidence in his own power to obtain sleep. The duty of the physician was to preserve the intelligence and the mental and physical activity of his patient, and this end could be attained if drugs were properly given, but if they were withheld a general deterioration might, and in certain persons would, result.

DISCUSSION ON PROPHYLAXIS OF MENTAL DISORDER

OPENING PAPER

BY

Sir HUMPHRY ROLLESTON, BART, K C B, M D,
Regius Professor of Physic in the University of Cambridge President
of the Royal College of Physicians of London

The widespread activities now in being to improve national health, the appointment of a Royal Commission on Lunacy Law and the recent movement in favour of mental hygiene make this an appropriate opportunity for a full discussion of the prevention of mental disorder. In the first place it is a matter not only of general professional interest and intimately connected with measures calculated to prevent all forms of disease, but is wrapped up also with child welfare, education, training, and even housing conditions. It is a branch of public health, and both of these two fields of activity will benefit from closer co-operation. A discussion such as this, though in a special section, should be on very broad lines, for it deals with the highest reactions of the human organism, in fact with its reactions as a whole, whereas in other branches of medicine one organ or system of organs chiefly, though by no means entirely, attracts our attention. The practical recommendations as to the desirable steps to be taken must be largely determined by the relative importance attached by experts in mental disease to the etiological factors, which still demand much more patient research. It is therefore perhaps right that the opening paper should be presented on general grounds, and it is certainly essential that the special knowledge of members of this Section should be brought to bear on a subject of national importance. The discussion will have an educational value for those of us who are interested rather in general medicine than in this special and rapidly progressive branch personally, I would express my debt to our President, Sir Frederick Mott, Dr Hubert Bond, and others.

It must be remembered that probably the bulk of patients in ordinary practice present some disorder, however slight, of mind, conduct, or feeling, spoken of as "nerves," neurasthenia, night terrors, and that in this early stage of conditions responsible for such an enormous amount of distress proper treatment is most successful. Failure to deal efficiently and sympathetically with these minor disorders, which no doubt depends on the very scanty instruction available in the medical schools on this subject, may well, as Dr J. A. Ellis Butler (1925) has pointed out, account for some of the vagueness of Christian Science and other forms of irregular practice. The public, as well as ourselves, require education as to the way in which mental abnormalities should be treated, and should be impressed with the similarity of mental and bodily disorders, and with the commonplace fact prevention is better and cheaper than cure, so that the earliest departures from the normal should at once be communicated to the doctor and remedial measures started without delay, this step eventually becoming as much a matter of course as a visit to the dentist. The enormous economic benefit to the country of such preventive treatment needs no insistence.

ETIOLOGY

The measures appropriate for the prevention of mental disorder are necessarily determined by the numerous forms of mental unsoundness. The multiplicity of the causes and of their divisions—hereditary, environmental, physical or bodily, and purely mental or psychological—complicates the problem of prevention which naturally appears in different aspects to the biologist, the physiologist, and the psychologist. The biologist regards heredity as specially important; the physician changes in the nervous system, and the psychologist independent alterations in the mental process. The influence of environment has a bearing on all three views—the hereditary, the neurogenic, and the psychogenic. Heredity and environment are closely interwoven in the causation of mental disorder, as predisposing and exciting factors respectively, the disease being the morbid reaction resulting from a complex

set of external agents stimulating "in inborn low margin of physiological resistance," and the abnormal response being determined either by the nature of the external stimuli or by the condition of the nervous and mental mechanisms. The special form of nervous disorder is not inherited as such, but there is a low state of vitality in which a tendency to hypersensitiveness is handed down, so that one of several manifestations, such as asthma, may occur, though different forms may appear in parent and child. The position is well met by G. Darpe's definition of the word "constitution," so vaguely and variously used in the past, as "the aggregate of hereditary characters, influenced more or less by environment, which determines the individual's reaction, successful or unsuccessful, to the stress of environment." Although, generally speaking, more can be done in the way of modifying the environmental conditions—namely, by all that is included under the term "mental hygiene"—measures to counteract gross hereditary disease such as syphilis and cretinism, must not be neglected. Abnormal mentality may obviously be due to change transient or permanent, in the nervous system, just as a hindage over the eye or a plug of wax in the ear will obscure sight or hearing, but this does not exclude the purely psychical factor of mental disorder in other cases, however unsatisfying this may be from the standpoint of the materialistic microscopist.

The influence of heredity in genius, crime, and insanity is fully recognized, and terrible examples, such as the Jules family in which the 540 legitimate and 169 illegitimate descendants of the original Max Jukes (born 1730) provide the most striking proof of the heredity of crime and of its relation to prostitution and mental disease. Half the cases of mental disorder have been ascribed to hereditary factors. This factor necessarily carries with it as means of prevention the difficult subjects of eugenics, sterilization of the defective, and birth control. Without being reactionary we may wisely hesitate before advocating strict eugenic measures of breeding which, if carried to their logical conclusions, might seriously impair the future progress of the race, for if the inborn tendency to variation, which is responsible both for mental weakness and for intellectual ability, were thus removed, a dead level of standardized men, like Rabbits' might conceivably result. Until, therefore, further research into this subject with its difficulties, especially the limitation of available material for the investigation of Mendelian factors in mental disorders, has thrown more light on a question which obviously conceals very great liberty of the subject, delay would be desirable. In the meanwhile the segregation of mental defectives provided in the Mental Deficiency Act (1914) has diminished the propagation of the handicapped child, and has to a limited extent met the question of sterilization of the mentally defective. Birth control, though a eugenic method, inasmuch as it tends to improve environmental conditions of the offspring, is less drastic and difficult than standardized propagation of the human race, and is, of course, widely practised though far more often among those whose offspring would be of value to the race than among the very poor, and thus has a dysgenic influence. But the Society for the Provision of Birth Control Clinics has established centres in Waltham and North Kensington, where poor married women are given advice on the safest methods of birth control by lady doctors. The arguments against this practice on the risk of a falling population and the moral one that promiscuity will be favoured the latter is the same as that which has made many sincere and well meaning people strenuous opponents of the prevention of venereal disease by "pickets."

While fully recognizing the indubitable influence of hereditary *dementia* it is not only natural but advisable to avoid exaggeration of such a fatalistic attitude by critical consideration of the limitations of this conception. Indeed, from the standpoint of preventive medicine it would be wise to minimize the view that heredity is so all-powerful that in the face of such a history all that can be done is to fold our hands in resignation. For a firm belief in the influence of heredity has much to answer for in stifling research in opposition to the belief that from his birth man is

in opposition to the belief that from his birth man is

endowed with instincts which rigidly limit and control his conduct throughout life there is the more or less mechanistic conception that man's actions are determined by his response and adaptation to environmental stimuli and that thus his instincts of self-preservation, sex, and the herd, are modified in either a good or an evil direction. What is often assumed to be hereditary may be really acquired in early youth as a result of the family environment and irresistible imitation which Dr C H Bond compares with an infection. An hereditary tendency may remain latent unless and until some stress is brought to bear on the individual, who then manifests symptoms of mental disorder, which in absolutely normal person would escape. The stress which is the exciting factor acts in virtue of the psychopathic predisposition, and may be (1) physical—trauma, infection, toxic factors, unhealthy environment, unsuitable diet, or (2) psychical—worry, emotional strain, overwork. As mental disorder may occur in its absence, hereditary tendency is not an essential factor in the etiology of insanity, though no attempt to minimize its importance as a disposing influence will be made. As would be expected, hereditary taint appears to manifest itself earlier in life than do mental disorders due solely to stresses—toxic infective, or physical. Carswell estimated that while 43 per cent of all cases have a constitutional basis, 67 per cent of cases arising between the ages of 15 and 45 years are thus explained.

Chronic infective foci, and the resulting toxæmia, by diminishing the resistance of the body and by producing degenerative changes in the nervous and endocrine systems, constitute an important factor both disposing to and even determining mental disturbance. Auto-intoxication due to oral, tonsillar, and intestinal infection is sometimes—for obvious factor, though often the local conditions—example, intestinal stasis or oral sepsis—are present without the appearance of general or mental symptoms, but this is probably because the resistance of the soil or the constitution as a whole, and especially of the nervous system, is sufficiently good to prevent any degenerative effects. This resistance may be broken down by chronic toxæmia, or the other hand, responsible focal infections, especially disease of the accessory nasal sinuses (P Watson-Williams), may remain latent and escape detection. Cotton (1923) believes that the so-called functional psychoses are due to a combination of many factors, the most constant of which, and from the therapeutic point of view the most important, is cellular disturbance in the cortex due to the toxins of focal infections, as evidence bearing on this he (1915) has found fatty degeneration in the cerebral cortex in the toxic-infective psychoses. He stated in 1919 that without infection the chances of psychosis developing is very slight. Local infections—the gall bladder and appendix—and of the genito-urinary organs are now recognized as important in causing mental disorders. At the New Jersey State Hospital, Trenton, the number of discharges increased from 37 to 85 per cent after removal of oral and tonsillar infections (H A Cotton, 1923). Watson-Williams has argued that systemic symptoms, including mental disorder, such as melancholia, may depend on infection of the accessory nasal sinuses, which being slight and not shown by profuse production of pus are unaccompanied by a protective polymorphonuclear leucocytosis.

The effects of alcoholism and syphilis and the means of obviating these factors, though not always carried out, are well recognized, and therefore need not be further discussed. It is very different with regard to epidemic encephalitis, for since its widespread prevalence, dating from 1918, it has been responsible for an amount of mental disorder the permanency and seriousness of which, though difficult at present accurately to estimate, are extremely menacing. It is probably due to a filter-passing microorganism, more information is needed as to the prevalence of carriers and their detection on the lines adopted by the Rockefeller Institute in regard to acute poliomyelitis, and as to the problems of immunization and of specific curative treatment. But the questions composing the "herpetico-encephalitic" group (Levaditi, Nicolau, and Poineloux)

require elucidation before further work can be done, Flexner and Amoss are investigating these preliminaries. Possibly in the future a test for the detection of susceptibility on the lines of the Schick test in diphtheria and of the Dick test in scarlet fever may be elaborated, so that prophylactic treatment, when such is available, can be utilized for the susceptible. At present no remedy of value is known, and the need for further research is therefore urgent.

An interesting question is the possible responsibility of primary deficiency of the endocrine elements of the gonads for mental disorder. Sir Frederick Mott has shown that changes in the sex glands occur in dementia præcox and other forms of mental disease, but it is difficult to disprove the view that the endocrine maldevelopment is concurrent, and, indeed, part of the general bodily arrest of development or precocious degeneration. Endocrine deficiency of congenital origin—for example, cretinism—may to some extent be prevented by ante-natal treatment and environmental precautions. Endocrine inadequacy arising later in life, in so far as it depends on focal infectious and toxæmia, should become less frequent with improvement in the general health of the nation as the result of school clinics and dental benefit in connexion with national health insurance.

The claims of physical and psychical factors as responsible for the causation of mental disorder have been much discussed, and no attempt to balance them will be attempted, for, indeed, they are too intimately related. The psychopathic element may be inborn as in hereditary disposition, or may be acquired during early childhood, and in either event may remain latent until and unless activated by physical or psychical causes. On the other hand, mental disorder may arise without any discoverable physical cause and be cured solely by psychotherapy, so while admitting to the fall that a physical cause may elude the most exhaustive clinical and laboratory investigation, the case for purely psychogenic origin in such cases is a strong one.

Educational Dangers at Schools

Overpressure in schools on clever boys likely to grind kudos for their teachers by winning scholarships is a widely recognized but somewhat neglected danger, and not infrequently leads to mental sterility in later life if—as is not uncommon in brilliant boys—there is an hereditary taint to some kind, usually mild in character, but in disorder. Precociously able boys will, of course, be in forms with boys considerably older, and therefore will be likely to share the same hours of sleep, whereas they require more, not only on account of their more tender years, but because of their mental activity. This should always be borne in mind by masters, who should see that such boys receive the quota of hours in bed corresponding to their age and not to their place in the school list. The importance of sufficient sleep and rest in the prevention of mental strain and breakdown is a point towards which the men attached to public schools are, I believe, fully alive, and their help should be invaluable. The need of an ample allowance of sleep for growing boys is often overlooked, and should be insisted on, as Dr T D Acland did so vigorously twenty years ago, the early school (from 7 to 8 a.m.), especially in the winter, may be of value from a disciplinary point of view, but hygienically it is open to serious question. At one school the question when early school should be stopped is wisely determined by the hours of sunrise. About puberty, especially in rapidly growing boys, and their for physical rest and a generous allowance of sleep is shown by the way they lounge about in easy chairs, and their apparent "laziness" in getting up in the morning in such a boy is "inattentive," "fidgety," "could do better if he chose," generally has the benefit of a hard to indifferent report, and "goes off his game," is not unnatural, and the wise parent should possess his soul in patience. Schoolmasters must recognize this and pay more attention to the personality of the human boy and not concentrate on his mental products. Boys are not sent to school to win testimonials to the transient success of a

forcing system. The senseless and harmful punishments of writing out hundreds of lines and keeping boys in after school hours should be regarded as relics of barbarism.

Great benefit both in the character of the work done and in the boys' health may result from providing or prolonging rest phases between classes, and, good though physical exercise is, a watch for stiffness due to overfatigue in rapidly developing boys should always be kept. To prevent breakdown and future mental disorder the master and the psychologically wise school doctor should consult and consent to work in unison rather than, as is not infrequently the case, arrive at a compromise while looking in the divergent directions of intellectual triumph, short-lived though it may be, and of *Mens sana in corpore sano*. Unfortunately, in the great public schools the assistant masters usually begin their career more or less as amateurs, and have to pick up wisdom while the pupils wait, whereas they should obviously receive as much training in their profession as do the teachers in the elementary and in some secondary schools. The desirability of taking a degree in the history and theory of education, or of obtaining a diploma or certificate in the principles and practice of teaching from the Board of Education, might well be considered. The pamphlet *The Practice of Health*, drawn up by medical experts in accordance with the resolution of the Headmasters' Conference in December, 1923, that every boy during his time at school should receive instruction in hygiene, is a valuable guide, and should help schoolmasters to do much for the physical welfare of their pupils.

Parents deputate much of their responsibility to schoolmasters, who therefore have considerable influence in making or marring character and future life though the contact is not so close as in the home. Bullies are not always confined to the boy's companions, and he who, with a thoughtless devotion to maintaining discipline, incidentally destroys a boy's self-respect should have a millstone hung about his neck and be cast into the sea. At private schools boys naturally get more individual attention but much care should be exercised in deciding on the age and stage of development at which a boy should be transferred to a public school where the strain for a highly strung boy of 13 years may exert a deleterious influence.

TREATMENT

Mental Hygiene—Although organized machinery for public health in this country dates from the middle of last century, and Sir John Simon's efforts at the Local Government Board, psychiatric prophylaxis, or mental hygiene has lagged far behind, and instead of this country leading the way, as it formerly did in the prevention of ordinary disease America has set us an example, largely by the enthusiasm of Mr. Clifford W. Beers. Our National Council for Mental Hygiene was founded in 1922, and has various subcommittees quietly at work, especially that on the prevention and early treatment of mental disorders. The possibilities included in mental hygiene are extremely numerous and concern the home conditions and influences bearing on young children and the education in this respect of the parents for the impress made by environment on the young mind is of the utmost importance, and as Henry Head has truly said, the mental hygiene of infants should be as carefully regulated as the ventilation of their nurseries. Family environment in the home even such potential incompatibilities, can often be tactfully set right by social service, and it cannot be too emphatically stated how much mental hygiene hopes to owe to non-professional help in this matter. Mental hygiene especially in the developmental period of life, is the first line of defence in the prevention of mental disorder and its want of failure is shown by the need for early treatment in psychiatric clinics which in their turn should preserve many patients from the necessity of having to enter mental hospital. The potential influence of heredity may be prevented from becoming active by wise adjustment of the environment. Further the treatment of early and recoverable cases afford the greatest hope of diminishing the incidence of confirmed insanity. The patients suitable for

mental hygiene include those who do not require certification, such as neurasthenics, the subjects of anxiety neuroses, and phobias, and also those who might be certified, but need not because they are willing to submit to treatment or are "non-volitional." As the National Council for Mental Hygiene pointed out in evidence before the Royal Commission, information as to the number of patients needing early treatment can be obtained from the reports of the Board of Control, the Prison Commissioners, the Registrar-General's return of attempted suicides, and the returns of the Principal Medical Officer of Health to the Ministry of Health as to the mental sequelae of encephalitis epidemica. The social adjustment of children suffering from the after-effects or epidemic encephalitis is a problem of growing importance for the workers in mental hygiene.

Early treatment in psychiatric clinics attached to general hospitals has many advantages: the education of the public to the recognition that mental disorder is intimately connected with bodily disease and not a distinct and mysterious condition, such as possession by devils, from the patient's point of view the avoidance of the stigma attaching in the public mind to residence in a mental hospital and especially to certification, the cure of acute cases without certification, the great facilities of complete pathological, surgical, and biochemical investigation of all problems presented by the individual patients, such as focal infections and disorders of metabolism, the advantage to the progress of medicine as a whole, and particularly with regard to the prevention of mental disease, for which object association with psychiatric clinics and social service is of special value, by bringing psychiatrists and general physicians into close and constant touch and here incidentally it may be mentioned that comparatively few lecturers on mental disorders in the medical schools are yet members of the clinical staff of the attached hospitals, though this is a logical sequence of the desired closer union of psychiatry with clinical medicine. Lastly, and not least, the treatment of mental cases in general hospitals will provide a much more satisfactory means of educating students, not only in mental disorders, but also in the understanding of the psychological aspects of everyday practice. In this respect the Anglo-Saxon race has seriously lagged behind the Continental countries. From a report of an investigation made by the National Council for Mental Hygiene it appears that out of 237 hospitals in England, Scotland, and Wales there are arrangements of any kind for early mental treatment in 24 only. A psychiatric clinic is incomplete unless it has attached to it beds for the more satisfactory treatment of the patients, and should be on the same footing as other special departments.

The main objection to the treatment of early cases in the wards of a general hospital is the inconvenience caused by noise, delirious, and violent patients in a general hospital. That these difficulties can be surmounted has been shown by Dr. J. D. Cornie's analysis of 500 cases of early mental disease treated in the Royal Infirmary, Edinburgh, where, however, the conditions are not those of the ideal psychiatric clinic. Of course discretion must be exercised as to the class of case admitted, and after some two weeks or so it becomes clear whether improvement from such treatment is probable or whether the case should be transferred to a mental hospital. It is an obvious advantage to have the wards for the mental patients in an annex and not actually in the same building and under the same roof as the general wards, they should be surrounded with gardens so as to make provision for open-air treatment, and connected by a covered corridor with the main hospital. In hospitals in the centre of London and large cities it may be impossible to provide grounds of sufficient size around a psychiatric block. As in the Henry Phipps Psychiatric Clinic attached in this manner to the Johns Hopkins Hospital and under the directorship of Professor Adolf Meyer the wards should be generally so arranged as to allow classification and separation of incompatible types of patients, to accomplish this and to watch the patients adequately so as to prevent accidents and suicidal attempts, a higher nursing staff than in the ordinary hospital ward is necessary. Other examples of successful psychiatric clinics are the Psychopathic Hospital, Boston, Mass., Professor C. Winkler's Neuro-Psychiatric Institute at Utrecht,

and the Maudsley Hospital in close contact with King's College Hospital.

The psychiatric clinic, which in order to disarm popular prejudice should be labelled "Nervous and Psychiatric Department," of a general hospital, should be closely connected up with a university, so as to provide facilities for research and for teaching medical students, and it would appear that in addition students interested in the experimental and other aspects of psychology would benefit from the opportunities thus provided. While a central laboratory in connexion with a psychiatric department attached to a general hospital and a university is the ideal arrangement, psychiatric or mental clinics situated at a distance from university centres should of course have clinical laboratories for routine work.

The prevailing note in the care of early and recoverable patients should be sympathetic conciliation rather than the forbidding coercion—cheerfulness and helpfulness instead of severity and repression.

GENERAL DISCUSSION

Dr HELEN BOYLE (Hove) considered that Sir Humphry Rolleston's opening paper was characteristic. It was on broad, fine lines, and ignored no side of the subject, which was wide as human nature itself. It was, however, lacking in one respect—it was so full and so true that in wishing to find something to dispute one was at a woeful disadvantage, and no discussion could thrive on complete agreement. Dr Boyle was in hearty sympathy with everything Sir Humphry Rolleston said (with one possible exception, which she would allude to later), but there were four points she wished to comment upon.

1. With regard to heredity, she agreed with his view as to the danger of eliminating all those who showed mental and nervous instability. Such heredity was feared too much. But they should address themselves to finding out if possible, as Dr Tredgold had said, what kind of instability indicated a degenerating stock and what a good and possibly evolving stock. With the exception of mental defect, all types of mind were valuable, even essential, if well adjusted to life. Quick reaction, a tendency to temper, and pugnacity might all be useful. Placidity and caution only would make life dull. The mean and selfish when adjusted, might be thrifty and pertinacious. Any virtue in excess was a vice. Any vice controlled might become a virtue. Moreover, no one yet had seen the perfect man. They did not know in what direction they ought to evolve. To aim at physical perfection in the hope of securing also good brains and character would be futile, for outstanding brain and character might be linked to an imperfect body. Even a Hercules indefinitely repeated would become boring! No breeder would attempt to breed without knowing what he wanted to produce. The most desirable qualities and powers might even yet be hidden, to be revealed later by what the opener had called "the unborn tendency to variation." In reference to birth control no one so far had shown how to avoid the danger that the thrifty, the thoughtful, the idealistic in every class would be the ones who would carry it out efficiently, and as had been said, "the limitation of a family often proved that that family should not be limited." Certainly there should be a strong public opinion against limitation

for selfish or class reasons, and the serious risk to only children must be borne in mind. It was doubtful if limitation for the sake of educational opportunity was of any value to the race.

2. The influence of the endocrine glands on mental and nervous conditions needed much investigation, not only as to the effect of disturbance of the glands on the mentality, but also as to the effect of disturbance of the mentality on the development and functioning of the glands. It was possible that "a primary deficiency of the endocrine elements of the glands" might be responsible for dementia praecox. It was also conceivably possible that a seclusive mental attitude might so shut off a developing personality from the external stimuli necessary to some glands, such as those concerned with sex, that they did not develop or function efficiently. It was known that other parts of the organism needed proper exercise and stimuli to develop and function. The effect of mental stimuli on glands, such as those concerned with the digestive tract was well illustrated by the dryness of the mouth which attacked those who feared public speaking. The view that "the endocrine condition was part of the general bodily arrest of development or precocious degeneration" was rendered doubtful by the fact that in some cases of dementia praecox the bodily development was good and showed the normal secondary sex characteristics. In manic depressive insanity was it not probable that irregular action of the endocrine glands was at least partly responsible for the alternating appearance of the symptoms?

3. As regards children and their education in adaptability, Sir Humphry Rolleston took and that mental hygiene in the developmental period of life was the first line of defence in the prevention of mental disorder. This mental hygiene might be briefly summed up in the quotation, "Nothing too much." In this country, who appreciating the worth of discipline and habit, the value of training in adaptability was perhaps less realized. Adaptability in its essence meant power and readiness to free life and extract from it and oneself the best possible results. A failure to adapt was the chief and earliest sign of nervous and mental difficulty. Especially with regard to sleep was this quality of adaptability desirable, and Dr Boyle would urge that from the cradle children should be accustomed to sleep, notwithstanding noise, light, talking, on any kind of bed, floor, sofa, as was convenient. This capacity was a priceless asset throughout life. The cult of the bedroom and its quasi sacred state was particularly noticeable in England. An Irish family of good social position recently came to stay with Dr Boyle, and, instead of cumbering themselves with a cot, they simply hauled out a bottom drawer, in which the baby slept peacefully. Adaptability as to meals was also good. A slavish adherence to time and quality in youth might be a nuisance later. Coeducation would seem to be a good way of teaching adaptability to sex problems. Time might be troublesome. Hypertrophied sense of time and punctuality was a curse in some families. Time should be given to children to use so that they might learn to handle it with sense. Observation was the most powerful assistant to adaptability. Without ready observation of external things and events it was impossible to adjust well to life. No one could adapt to what he did not see. An evil in the path of many children was the large size of the classes in the council schools. The egocentric, seclusive, quiet little boy who did not fidget or rrg was perforce allowed to sink into himself while the teacher controlled the noisy elements, who were really in less need of attention. This might be an element in the causation or encouragement of dementia praecox.

4. General measures. There was no subject which needed greater mutual understanding and the co-operation of all classes in the community. This could probably be best attained by a body such as the National Council for Mental Hygiene, mentioned by the opener, in which the medical profession, educationists, criminologists, psychologists, social reformers, employers of labour, and labourers could all co-operate and meet on common ground. The necessity for psychiatric clinics was assented to by all. It was with a remark of Sir Humphry Rolleston's in this connexion that Dr Boyle felt she might not be in accord

He spoke of "the cure of acute cases without certification." If by this he approved of the admission of acute manias to psychiatric clinics she felt very sorry. To her mind it was essential to keep the clinics free from such cases, or the same stigma would shortly attach itself to the clinic that he feared in connection with the mental hospital. Mental hospitals were in some cases, and should be in all which admitted acute cases, so guarded and have such clinical facilities that they would not be surpassed by a clinic. Such was the Holmoro Mental Hospital, which Dr. Boyle recently had the opportunity of seeing. In relation to the clinics, extended and trained social service was necessary.

In conclusion, Dr. Boyle suggested that their aims should be

- 1 The establishment of psychiatric clinics at all general hospitals for willing nervous and mental patients
- 2 Efficient and well equipped mental hospitals for patients whose liberty had to be curtailed
- 3 A trained social service
- 4 Improvement of educational methods and of environment
- 5 A strong and representative National Council for Mental Hygiene

Dr. BERNARD HART (London) said that Sir Humphry Rolleston had emphasized the principle that rational prevention was necessarily dependent upon a knowledge of etiology. This principle held as rigidly in mental disorder as in any other sphere, but unfortunately in the etiology of mental disorder their knowledge was uncertain, and it constituted a battle-ground for innumerable disputes. Not only were there two great camps—the physiogenic and the psychogenic—in which an almost exclusive weight was given to causal factors of a physical and psychological order respectively, but each of these camps was subdivided into smaller camps. On the one hand were the adherents of toxic, endocrinological, hereditary, and other physiogenic theories of causation, while the psychogenic schools were similarly subdivided into many groups of varying size and degree of incompatibility. The analytical schools alone included such radically different etiological theories as those of Freud, Adler, and Jung. In all this welter of opposing views it would be difficult to find a single factor concerning whose significance general agreement could be obtained. In these circumstances the conclusion would seem to follow that the problem of prevention would present a corresponding uncertainty, that the different schools of thought would advocate different and more or less incompatible procedures, and the devising of practical measures of prevention thus become a hopeless task. There was certainly a measure of truth in this conclusion, and it counselled a curie in the devising of any drastic procedures. Particularly, as Sir Humphry Rolleston had pointed out, did this apply in the sphere of eugenics, but a similar caution might be advocated in other spheres. Nevertheless, the conclusion that all effective prophylaxis was impossible, because of their etiological ignorance, went too far. Although their knowledge was inadequate and fragmentary they had in many cases indisputable evidence of certain factors playing a causal part, and it was significant that those factors were in one place of a physical, in another of a psychological, in a third of an hereditary order. It was certain that a toxic agent like alcohol could directly produce temporary or permanent mental disorder, that psychological factors could produce morbid pictures of the type they saw in the psychoneuroses, that if they married two imbeciles they would produce mental defect in the offspring. They had in these instances paradigms, as it were, of different types of causation, and they had overwhelming evidence that no one-sided interpretation of the etiology of mental disorder, no interpretation which failed to take into account these patent facts, could possibly be sound. The error of all these one-sided interpretations—of the pathologists who talked of psychology as an *ignis fatuus* of the psychologists who sneered at the naive materialism of the pathologist—seemed to Dr. Hart to lie in the failure to appreciate that mental disorder was something essentially different from the disease entities of general medicine. In mental disorder there were no disease

entities, there were only types of reaction—the reaction of the entire psycho-physical organism to its internal and external stresses—and these types of reaction formed a continuous series, ranging from the ideal normal to the major psychoses, with no sharp lines of demarcation, and no possibility of exact classification into discrete entities. Here and there throughout this continuous series they had paradigms of causation of the kind he had mentioned—conclusive pieces of evidence that physical, psychological, and hereditary factors might all play a part in producing the clinical picture before them. So long as they clung to the notion of discrete entities these apparently disparate factors could not be combined in a unitary conception, and they were lost in a welter of futile controversy as to whether mental disorder was essentially of physical or mental origin. But if they kept in mind that it was a final reaction of the whole psycho-physical organism to its internal and external stresses, they had no difficulty in conceiving that all kinds of factors, physical and mental, might co-operate, and that the final result might be altered and possibly abolished by attacking any one of these co-operating factors. Hence there was room for the pathologist, the psychologist, and the biologist, and the first great need for the attainment of an adequate knowledge of etiology, and therefore of prevention, was mutual tolerance and understanding.

Moreover, such fragments of knowledge as they already possessed in any of these spheres could be applied to the devising of prophylactic measures. But as their knowledge was as yet so fragmentary, not much could be done along these lines at the present time, and the development of efficient prophylaxis must be looked for as an ultimate and natural result of progress along other lines. These other lines were research and provisions for early treatment. The need for the former required no emphasizing, and that for the latter but little more to those who were aware of the facts. The two needs were, indeed, intimately bound together, because research would only grow in the conditions which favoured it, and of these conditions the material for study, and clinical observation which accompanied provisions for early treatment was an indispensable part. Yet the actual state of affairs with regard to these matters was in this country little short of a scandal. Research struggled in a few centres, mostly divorced from the medical schools, with which it should be intimately allied. Expensive homes for the treatment of the early psychoses and the psychoneuroses existed for the wealthy but, except for a few scattered institutions like the Maudsley Hospital, and here and there out-patient departments which must be inadequate because they had no beds or equipment, there was nothing for the poor. It was in these directions that effort and organization must first be directed if they were to advance their science, and the supreme need for the development of efficient prophylaxis was to establish conditions in which knowledge of etiology and of the effects of treatment could grow—something really comparable to the conditions which the medical schools had provided for general medicine.

Dr. E. MAROTTER (London) proposed to indulge in some general doubts, and to enter a plea for scepticism. He had expected there would be a vacancy for the post of devil's advocate, but Dr. Hart to some extent anticipated him. He wished to ask whether strictly between themselves they might not admit that they had no definite information on the prevention of mental disorder. The very contrary of his view was so widely upheld that it seemed worth while to consider, first, whether it was true, and, secondly, whether, if true, it was expedient. To begin with, one should be clear as to the difference between prophylaxis and early treatment between measures taken after appearance of the earliest symptoms and designed to arrest or modify their progress, and, on the other hand, measures designed to prevent occurrence of even first symptoms. True prophylaxis must depend on reducing internal susceptibility or exposure to external causes of a disease. The distinction between true prophylaxis and early treatment in regard to mental disorder was not a quibble, it was just as real if not as obvious as in a case of cancer or syphilis. It was practically important because their demands for public help

towards early treatment could reasonably be based on moderate claims regarding their powers, while appeals in aid of prevention should be founded on their almost total ignorance and impotence as in the case of cancer. Dr Mapother desired to emphasize that they were not yet even in a position to collect indisputable evidence satisfying scientific requirements regarding any method of prevention or early treatment. As Sir Humphry Rolleston had said, they badly needed in psychiatry something analogous to the Schick test for susceptibility to diphtheria. In fact, Dr Mapother thought a prodromal or prognostic test of that kind was the necessary foundation of any real scientific progress in psychological medicine, and it was certain that neither psychology nor material pathology yet provided such a test. If ever they got one it was certain to be quantitative. But so long as they lacked a definite criterion of the psychopathic constitution (existing before symptoms and, if untreated, constantly followed by them), so long would the effect of any alleged prophylactic measures be quite uncertain. Even in respect of early treatment, so long as no test told them whether a mental syndrome, if untreated, was destined to progress or arrest, so long would the *post hoc ergo propter hoc* fallacy enjoy its accustomed vogue and opinion more or less disinterested do duty for evidence. One of the most useful functions of the clinic of the future would be the effort to establish a basis for determining the value of treatment by following the ordinary clinical course in patients attending it from the start of symptoms and correlating this course with the earliest psychological or pathological tests in the laboratory. The foundations of such an inquiry were being laid at the Maudsley Hospital. Three-monthly inquiries were sent to ex-patients or their relatives, and, failing an answer, to the doctor who had recommended the case. Answers as to progress were obtained in the great majority of cases.

The workers in the laboratory under Dr Goll's direction had found certain anomalies in the reactions of the autonomic system to experimental stimuli (such as the taking of food and posture) which were practically constant in well marked cases of mental disorder belonging to the so-called functional group. Among these reactions one might specially mention changes in the absolute and relative leucocyte count. The anomalies were independent of the exact form of symptoms and particularly of the conduct. So far this was a real advance. Many of the persistent physical changes described in such cases were in no way fundamental but rather parallel to the conduct. Such pathology amounted to an elaborate confirmation in the laboratory of what was obvious to the man in the street. Unfortunately, these anomalies, while constant in advanced cases, were not so in doubtful ones—for example, a test which was constantly positive in advanced cases of dementia praecox was tried in doubtful cases of the same kind where guidance was needed. Subsequent inquiries about the progress of this doubtful group to date showed that neither a positive nor a negative reaction had any clear prognostic usefulness as yet in those cases where it was needed.

Admitting the lack of any prognostic laboratory test, how far did personal experience or the collective expressed in statistics enable one at a really early stage of neurosis or psychosis to forecast the outcome? How far did consideration of the causes or clinical symptoms enable one to prophesy the course, if untreated, in individual cases of the functional group with such certainty as to establish the value of any treatment? Dr Mapother could not discuss prognosis at length, but the chief lesson of experience, he considered was caution. Personally, he thought the longer, and especially the wider one's clinical experience the less one's conviction that it was possible to give forecasts before or even very soon after the start of symptoms that might be the beginning of a neurosis. Abstraction, apparent stupidity, moodiness, wariness, preoccupation with fantasy might represent the beginning of dementia praecox, but a phase of such symptoms was almost normal in the adolescence of anyone with sufficient imagination to be much use later. What real evidence was there that the symptoms described, for example, in Dr Hector Cameron's excellent book on the nervous child, were often the precursors of serious neurosis or psychosis later? Some permanent cases of dementia praecox developed abruptly,

others, with apparently identical onset and symptoms, entirely cleared up. The facts indicated that claims to success in prevention or even early treatment based on results in a few cases were unproven—to put it charitably, they were merely the opinion of a biased optimist. Comparison of results in two long unselected series of cases with and without some very definite treatment, if subjected to rigid criticism, might prove something. So far as he knew, no such statistical comparison existed.

So far Dr Mapother had merely tried to show that a doubtful opinion was all anyone could possibly express at present regarding prevention. His own opinion, for what it was worth, was that their powers were extremely limited. Prevention directed to endogenous factors was almost impracticable. As Sir Humphry Rolleston had said, eugenics were not practical politics at present. Practically all measures of philanthropy were dysgenic, though their effect in lessening external stress on the individual might more than counterbalance this. So far as he knew they had no power to modify deviations of the normal changes accompanying adolescence, childbirth, or the climacteric or the occurrence of premature senility. Considering external factors, the mental results of well defined bodily disease and of such symptoms as pain and sleeplessness could be largely controlled. But it was clear that, as regards alcohol and syphilis, true prophylaxis (that is, reduction of their influence on the hitherto normal) was a problem of national policy rather than of psychological medicine, and, after all, though such causes produced some of the worst cases of mental disorder, they were relatively few in the whole mass of neurosis or psychosis. As to reduction of mental stress before symptoms appeared, he confessed to doubts. Some of the more obvious and wholly vicious strains might be avoided. They were past the days when children were terrified with tales of ghosts and hell, and perhaps they might hope to pass those in which they were frightened with fables about masturbation. But in any large war psychosis prophylaxis was impracticable. Life would always provide the match for an explosion where the charge of predestination was high enough. The provision of circumstances and conventions to which the neuropath could adapt must be the business of the community, and fortunately there seemed little fear of the community framing its requirements to suit the neuropath. Competition would always involve the risk of a breaking strain, and the price of safety for the neuropath would be acceptance of the secondary and remuneration of what made life worth while. Was it justifiable to advise such a course in the absence of very definite symptoms? Dr Mapother had every sympathy with Sir Humphry Rolleston's jaded schoolboy, but one met more difficult cases—for example, one recently of an under-graduate holding a scholarship at a university working for the Indian Civil Service, with no prospect of a comparable career if he gave up. He thought the advocates of the policy of passiveness should not forget that the world owed some of its best achievements to the work and overwork of people with neuropathic ancestry and constitution facing the risk of breakdown.

Dr T. A. Ross (Penshurst) considered that the most important thing was to get medical students interested in the psychoneuroses, which were really minor mental disorders. At present the students were interested in physical illness only, because their teachers were. There were too few psychiatric clinics in connexion with the large teaching hospitals, and even where such clinics existed they were in obscure parts of the hospital and students did not attend. In consequence, when these students became practitioners they did not know what to do with psychoneuroses, and were inclined either to pass over or neglect these patients. There were many cases of this kind who needed care for years much in the same way as did cardiac cases—not continuously but at times—at periods of extra stress when there was the slightest threat of breakdown. It was not possible that this matter should be undertaken by specialists or institutions; the cases were too numerous and the duration of the disorder too lengthy. The patients needed support for a long time, and therefore the bulk of this support must be given by the general body of practitioners.

Dr W A POTTS (Birmingham) said that he could not accept the somewhat pessimistic attitudes of Dr Bernard Hart and Dr Mapother. Certainly much more detailed investigation and knowledge was necessary, but Dr Hart had himself given a complete conception of the etiology when he said that the factors in mental disorder were (1) physical, (2) psychogenic, and (3) biological. There was universal agreement that infections, often of a slight nature, were exciting factors, and must be dealt with first. The success of treatment along these lines depended on the thoroughness of the preliminary investigation and the adequacy of the subsequent treatment. After dealing with this side, which sometimes was all that was required, some form of psychotherapy must be employed if necessary. Here again, Dr Potts believed, in spite of the obvious divergence of various schools, there was general agreement that the abnormality dated from very early life. Dr Potts wished to dissociate himself from the idea expressed by Dr Mapother that alcohol and syphilis, important factors in producing mental disorder, were really questions of national policy, such as was the business of the medical profession to inform and direct national policy on such matters. He thanked Dr Helen Boyle for drawing attention to the importance of training in early life in adaptability and observation, his idea was that the places for the prevention of mental disorder were the ante-natal clinic and the nursery.

Dr P WATSON-WILLIAMS (Bristol) stated that, however strong the conviction that infection and resulting toxæmia was the determining cause of a large percentage of insanity, infection obviously played no part in the larger proportion of mental aberrations. But it was the former and highly important group to which he wished to refer, because if, by the detection and elimination of focal or other infection, the occurrence of mental unsoundness could be prevented, relieved, or absolutely cured, they should leave no stone unturned to utilize the means they had at their command in treating such cases. Forty years ago, when a medical officer in an asylum, the toxæmic factor as the sometimes essential cause of insanity became evident to him, later the effect of sepsis in the nose, throat, or ear in causing mental depression, neurasthenia, suicidal impulse, or definite insanity, was also obvious, because the psychosis was almost consistently overcome by the successful removal of the exciting sepsis, and some of the crises of marked insanity with delusions were among the most successful. Dr Watson-Williams maintained that there was no line of demarcation between the slightest mental deteriorations of neurasthenia and well marked and certifiable insanity from sepsis, every gradation was to be met with, and many could be prevented in the early stages from becoming mentally unsound by proper treatment. He could not agree with Dr Mapother that because, as he said, they had no "definite information as to prevention" they should hesitate until they could elaborate some test as a criterion of susceptibility corresponding to the Selick test for diphtheritic susceptibility. This was unnecessary, and if such a criterion was available it would be of little service, because the child susceptible to septic infection, and therefore suitable for inoculations, might, and often did in time become auto-immunized by existing infection while those found non-susceptible might become so at any later period—as for instance, by an influenza attack. He wished to stress the importance of thoroughness in the search for a suspected focal infection, most scrupulous care was needed, because it was latent or cryptogenic foci particularly that were prone to cause chronic toxæmic conditions. When there was a copious purulent, and therefore obvious, discharge there was much local reaction and little tendency to toxæmia, but when the infection was associated with but little discharge, and that non-purulent or only opalescent and difficult to observe toxæmic symptoms were more prone to arise. This difference he attributed many years ago to the inhibitory effect of the profuse outpouring of polymorphonuclear cells in copious purulent discharge, whereas with similar infection the absence of polymorphonuclears allowed the toxins to be absorbed. Hence a well marked protheca alveolaris was more distressing locally

and more obvious than the much more dangerous apical granuloma of latent dental sepsis, similarly a post-mortem wound which suppurated was much less dangerous than the local infection which crept up the lymphatics and was so prone to cause general blood poisoning.

The examination of the nose, throat, ear, or teeth must therefore be carried out with meticulous care so that they could feel assured either that in these regions there was, or on the other hand, definitely was not, a source of infection. Moreover, it was necessary when a possible source of infection had been found to avoid jumping to the conclusion that no other and perhaps more potent source of infection lay in other regions. One had but to realize how far-reaching the results of such infective causes of mental deterioration might be, and too often were, to grasp the immense import of the detection and treatment of these conditions. It was not only the actually insane that were concerned, but the immense numbers who were mentally abnormal. If such conditions were capable of effective treatment they could imagine the enormous loss to society and to the State incurred by failure to treat them—the loss of initiative in the business man, the unhappiness and distress in many a home, the loss of working days to the labourer, the blighting of the mental development and educational chances of the child—and thus the importance of the subject of the discussion which had been introduced so ably in this Section became all too manifest. Most mental institutions required reorganizing so as to place them on a footing with modern hospitals, and the medical superintendents should be relieved of too great a burden in administration while the collaboration of physicians and surgeons in various departments should be more actively ensured than hitherto had been possible.

Dr H CRICHTON MILLER (London) said that he had listened with interest to the references made by several speakers to the role of infection in causing mental disorder. The views held by Cotton on this subject tended perhaps to give a one-sided outlook, and to regard focal sepsis as the cause of most functional disorders. It would be more correct to think of toxic absorption as a very prevalent condition in mental disorder. The trouble was that only a minority of practitioners seemed to recognize the importance of cryptogenic infection to which Dr Watson-Williams had referred. The speaker went on to give the results of certain investigations among functional cases. Last of all, temperature readings had been relied on as an indication of latent sepsis. This method might be reliable with ordinary patients, but in neuropaths was misleading. Then the sedimentation test was used for a period with wholly unsatisfactory results. Now the blood picture was relied on as the chief evidence of toxicity. Of a consecutive series of 133 admissions to his nursing home 62 per cent showed a leucocytosis, while a relative lymphocytosis was found in 66 per cent. The average readings for this group were as follows: Red blood corpuscles 5,010,828; white blood corpuscles 9,940; haemoglobin 82 per cent; colour index 0.82; polymorphonuclears 57.7 per cent; lymphocytes 34.8 per cent; hyaline, etc., 4.1 per cent. There were good grounds, therefore, for regarding bacterial infection as a definite causal factor in a majority of such cases, and as such it should be dealt with thoroughly without in any way prejudicing other therapeutic measures.

Dr C MORTLOCK-BROWN (Barnston) insisted upon the importance of fresh air, freedom from noise, and the avoidance of alcohol in the prevention of mental disorder. Greater care should be bestowed upon the education and upbringing of children. As regarded birth control, self-control was better. Finally, she entered a plea for the appointment of medical women to the Board of Control.

Dr R M CRAIG (Torquay) gave particulars of two psychiatric clinics—attached to general hospitals—with which he was associated. There had been great difficulty in starting the clinics owing to local medical opposition, some saying that there was no need for such clinics and others that patients would never go to them. The success of the clinics had entirely disproved both these statements.

Dr M L C Mingshon (London), in dealing with the educational factors in the prevention of mental disorder, was strongly of the opinion that children should not be pushed intellectually beyond their powers. The amount of their work should be strictly limited and long hours avoided. An overstudious child often ended in mental breakdown.

The PRESIDENT (Sir Maurice Craig) expressed on behalf of the Section their indebtedness to Sir Humphry Rolleston for being present and their appreciation of the extraordinarily able way in which he had opened the discussion. In this Section this year they had endeavoured to keep free from pure specialism, and to this end Sir Humphry Rolleston had helped in no small degree. What he had said was full of important matter, and with his general outlook on the subject all should agree. The discussion had been kept at such a high level and the ground covered had been so wide that any attempt to sum up would be taking up time for little purpose. For himself, Sir Maurice Craig took an optimistic outlook as regards the prevention of mental disorder. He felt that even with the somewhat fragmentary knowledge that they had, if they used it to the full there would be an appreciable lessening of nervous and mental disturbances. He had long felt that to do the most good they must get back to understanding and protecting the earliest years of life of the child. To him hypersensitivity, with its quickness of response, was the factor of most moment. Hypersensitivity meant hypersensitivity to everything—environment, certain foods, drugs, and exogenous or endogenous toxins, and, further, he believed that fatigue rendered the exhausted tissue cells or the organism as a whole more liable to these stresses, more especially to the poisons. By overwork they really meant overstimulation, and it was this that was so harmful. There was one matter that had not been referred to, and yet it was one upon which Sir Maurice ventured to think that all agreed, and that was the preparation work that children had to do at night. With the day scholar it led to disturbed emotion when ordered to bed by a parent, and with the boarder to the taking of books to bed in order to start work as soon as it was light. Sir Maurice regarded evening preparation as one of the main causes of fatigue symptoms in many children, for, apart from the actual stress, it led to defective quality in the sleep and all the concomitant disturbances that followed.

SECTIONS OF DISEASES OF CHILDREN AND OF PUBLIC MEDICINE

ROBERT HUTCHISON, M D, F R C P, in the Chair

DISCUSSION ON RHEUMATIC INFECTION IN CHILDHOOD

EARLY DIAGNOSIS AND PREVENTIVE TREATMENT

OPENING PAPERS

I—E J POINTON, M D, F R C P JOND,

Physician University College Hospital and the Hospital for Sick Children Great Ormond Street

I must first thank you for the dangerous honour you have done me in asking me to assist in introducing this discussion. Dangerous it is, because Bladud, who discovered your mineral water springs, was a great necromancer, and to speak on the prevention of acute rheumatism here may lead me to a mysterious fate. Fortunately, I remember that Bladud was also the first British aviator, and a man who is sufficiently enthusiastic as a pioneer to break his own neck on the Temple of Apollo will, I believe, be kindly disposed to an introducer of a discussion on what I believe to be a progressive movement. Nevertheless my task is no easy one for so late as 1923 a very similar discussion was admirably introduced at Portsmouth by one of your Vice-Presidents Dr R Miller. I am, too, in the position of one who has already overthrown himself upon the subject, and we know that knowledge advances much more slowly than the writing of papers.

This, however, may truthfully be said, that there is

probably at the moment no issue in practical medicine more important and more full of possibilities than the prevention of the acute rheumatism of childhood. Instance only the heart disease, and let us examine our position. Is there a doctor here to-day who is practising in the large towns of this country who will not agree that it is a frequent event under 12 years of age, and a great cause of suffering and early death? Is there a doctor here who has not been impressed by the great recuperative power of the heart in the young, if it is only rested and protected? Are there not many people with organic rheumatic heart disease living quiet, useful lives, and often doing more for the community than many a headstrong hile citizen who squanders his life in riotous living? Again, who is clearer so frequent among school children in our large towns? Surely there must be some discoverable factor that is stimulating their nervous system, and in any case the problem is one deserving of the closest attention by all interested in the young.

But when I think of the prevention of acute rheumatism I am not so sanguine as to imagine that in the near future we are going to eradicate this disease. How much may be relieved in years to come I do not presume to foretell, but at the moment only see this, first—that by more careful organization, greater supervision, and by more widespread study, we shall prevent much of the harm that this disease is doing, and if we do not advance along these lines there will continue to be the present wastage, not only of life, but of useful citizenship.

Now my part is not concerned with the aspect of the problem that confronts the medical officer of health, and I am delighted to find that this subject is placed in the rightful and skilled hands of Dr Aslins. I have to open this discussion with a consideration of the early symptoms, and to give such indications as I can to further the clinical side of prevention.

It also appears to me that there is a certain distinction to be made between dealing with our subject as a physician in charge of a hospital ward and discussing it on the broad lines that we are concerned with to-day. In a hospital we aim at fine distinctions, in the hope of throwing new light upon disputed points. But for our purpose I think the first essential step is to come to a more or less clear decision upon the symptoms we consider good evidence of acute rheumatism. It is far better, I think, when working on a large scale, to deal with clear cases of acute rheumatism than clog a new machine with a mass of indefinite illnesses which may, or may not, be rheumatic. There is a great amount of organization and inquiry to be expended upon obvious rheumatic heart disease, chorea, recurrent arthritis, the difficult question of the tonsils and other sites of infection, and upon the factors which govern renewed attacks of rheumatism. When the machinery is in better working order the more intricate problem concerned with borderline cases will then naturally come into the field and can be dealt with more easily.

So also with prevention it seems wiser to me to deal first with cases which promise a good chance of useful recovery than with those which are very seriously damaged, for we may hope to diminish in the future the number of severe cases, if we can do good to the mild ones. Let us suppose, for example, a county hospital established for prolonged rest, supervision, and education—such a hospital must of necessity be limited in capacity. It would be better to use this for children recovering from first attacks of rheumatic heart disease or from slight damage rather than to fill it with chronic cases of severe valvular disease. It is useless to shut our eyes to the difficulty of expense, and such being the case we must make the very best use of the opportunities we possess, and if we undertake some new step we must be able to produce clear data that we have done practical good to the children. Then, in course of time the public will appreciate the fact and more money will be forthcoming for the difficult cases.

In the Bradshaw Lecture last year I endeavoured to show how much machinery we have already in steel, waiting to be more accurately fitted together: the general supervision by the practitioner and hospital, the useful danger signals of the school medical officers and other official examiners, and so on. Since that lecture was given I have had an

opportunity of collecting some facts upon the rheumatic children in a country hospital in which an arrangement was made with the London County Council for their education.

The Invalid Children's Aid Association has for a long time been making pioneer efforts on these lines, and last year opened a hospital at Hailfield in Sussex for girls up to 15 years of age and small boys. As one of the honorary staff, and with the kind permission of the council and my colleagues, I am enabled to make a brief allusion to the year's work. There were 123 cases admitted in the year, and though they were all rheumatic children it was not until the first week in March, just at the end of the twelve months, that two of them, after a period of much cold rain, developed fever and rheumatic pains. In London meantime, from October, 1924, onwards I was having many cases of active rheumatism, some with general pericarditis, admitted to my wards. J. W. G. Prince, the medical officer to the hospital, writes:

"Despite the bad weather conditions and the stringency and exposure in their new lives the children did wonderfully well. Taking the cases as a whole, one might say all have benefited greatly and many remarkably. The length of stay of the children varied from one to twelve months and the average was five months. Many expressions of appreciation were given or sent by the parents as to the improvement in their children."

Now we can be sure that, in any but the most severe cases of cardiac disease in childhood if these children show no signs of active rheumatism and are improving in their well-being, the compensation and reserve power of the heart are increasing, and so we can justly state that these children derived much benefit from their stay.

None of us consider that this home is perfect for its purpose, for it is of the nature of an open-air hospital, though open in its essential the damp inclement nature of our climate necessitates special precautions in dealing with the rheumatic.

No worse ven for a strait, so far as cold damp was concerned, could have thought us, but I consider the results have been most encouraging. It has convinced me still further that the prolonged cure of rheumatic heart disease, in its early stages, after the acute phase is over, should be carried on in the country. These children will then gain remarkably in health and strength and their cardiac condition will also greatly improve. Further, it proves that suitable educational measures will add much to their happiness.

I am often asked, Will these measures prevent relapses in the future? The answer seems to me plain, until we have a specific remedy the most we can expect is that by giving the children time to consolidate the recovery of their hearts, and by assisting Nature to build up the resistance of their body tissues, we certainly help them to repel future attacks. After puberty the tendency to cardiac rheumatism diminishes, and thus we have the right to believe, until it is proved to the contrary, that a number of these cases will escape further attacks. If, however, their home surroundings are unsuitable we cannot hope at present wholly to succeed, and it is not a reasonable expectation. But it is reasonable to expect that further study in other directions will teach us what surroundings are particularly detrimental to these children, and to find methods for modifying them. Fresh air, rest, and education will not themselves arrest further rheumatism, but they are sure steps in its prevention.

In an ideal hospital we should be able to protect them more effectually from exposure, also to learn much of the recovery power of the heart and to devise methods to favour such, but this means funds for the necessary investigation and for the planning of buildings and grounds most suitable for such children and these inquiries, further, we are not going to achieve more complete success until experience, time, and money have been laid out in many directions, for we are faced by the difficult problem of a recurrent disease is yet imperfectly understood. This is, however, clear—that if the policy of graduated rest, fresh air, and education in country surroundings is a step forward in prevention, the only problem confronting us upon this particular aspect of the subject is whether the public is justified in spending the money required. That problem I do not pretend to

settle, for it turns, on the one hand, upon what value the public attaches to the relief of suffering, and to giving children, victims of rheumatic disease, a better chance to become useful citizens, and on the other hand the extent of the conviction of the medical profession that such a step is a sound one, this latter point is, I take it, one of the reasons for this discussion.

Now it is clear that an essential part of the general problem must be a knowledge of the more usual ways in which acute rheumatism develops in the child, and though I have no hesitation in stating that at present there is no specific test, and that many cases at first cannot be diagnosed with certainty, I am also convinced that a great number follow along well known lines. The chief manifestations of the acute rheumatism in childhood are well known—they are (1) carditis, (2) chorea and other nervous disturbances, (3) arthritis and fibrositis, (4) tonsillitis, (5) nodules, (6) skin eruptions, (7) pleurisy, (8) anaemia, (9) hyperpyrexia. There are others, which I accept, but are disputed, and with them I will not delay.

But it is not sufficient for our purpose merely to know these manifestations, we also want to know their relative frequency and their more usual combinations—in other words, the modes of onset of this disease. I have records of 1,108 cases of acute rheumatism in children under 12 years of age in whom, as far as general inquiry could ascertain, the attacks were first attacks. These cases showed carditis in 673, arthritis in 626, chorea in 617, sore throat in 344, nodules in 94. I do not suppose that every case was a first attack, in spite of my efforts to ascertain this fact, but such a large number is sufficient to give us a definite idea of the relative importance of some of the most serious manifestations.

I have found that a great number of these cases of acute rheumatism developed along these lines: (1) those beginning with sore throat, arthritis, and morbus coelis, and (2) those beginning with chorea, and often with morbus coelis also.

There is another group, fortunately a small one, which commences with great severity, and within the period of a few weeks develops all the worst manifestations. Such are most frequent in the younger children and in those with a strong family tendency. These may commence with fever, vomiting, diarrhoea, and sore throat, then there develop arthritis, carditis, nodules, rapid anaemia, and even chorea. Death may occur in this first attack from carditis, or recovery leave the child mortally injured. For us, to day, this group is of secondary importance for from the first they are gravely ill.

There is a third group, not so acute, in which the symptoms are definite, but subside, though not completely, fleeting pains may remain here and there, and if the child is allowed to get up shortness of breath develops, step by step the disease unfolds, and we find ourselves faced by a relapsing type of illness which ends in what is termed "the rheumatic state." We are met with a very real difficulty in this group, for we may not be able at first to foresee the evil tendency of the disease. May I give one word of warning? It is very easy to overlook in such cases the first early dilatation of the heart, and yet this may be the key to the situation.

Next we come to those cases in which one manifestation is predominant—I do not say absolutely solitary, but attracting all the attention. The most frequent type of this group is chorea. When we are painting the picture of rheumatism with the brush of the scenic artist it is advisable, I think, to consider all cases of chorea as of that origin. There are exceptions, but they are not sufficient to alter this attitude. In support of this, I analysed a series of 217 of my cases of chorea, 122 had clear evidence of heart disease and other rheumatic manifestations, 28 more had arthritis and muscular pains, 22 dilatation of the heart, and 10 followed a sore throat. 20 gave no history, but later 2 developed active rheumatism, 15 were attributed to fright and shock, but 2 afterwards were certainly rheumatic.

In another series of 104 cases chorea was the solitary manifestation in 37, but 12 of these subsequently developed active rheumatism. I have had a child under treatment for chorea five times die eventually in the sixth illness from rheumatic carditis. The view that fright is an outstanding

cause of chorea was for ever laid at rest by the fact that it was less frequent in London during the year of severe raids than in a subsequent year when there was an outbreak of rheumatism.

From the aspect of prevention I attach great importance to chorea, for this manifestation gives us the best clinical evidence of the behaviour of rheumatism in the human tissues. It is also frequently associated with the most important of all cardiac lesions—mitral stenosis. Lastly, it suggests nerve overstrain as a factor predisposing to acute rheumatism. I need hardly remind the doctors who practise in this city how frequently evidence of nervous exhaustion is discovered in the allied disorder rheumatoid arthritis. I am convinced that a widespread inquiry, by school medical officers, into the subject of chorea would supply us with valuable information.

Heart disease is a predominant or solitary manifestation of even more vital importance than chorea. Coming now as we do to what I believe will prove in the future one of the greatest difficulties in the problem of prevention, I venture to introduce this section with three dogmatic statements: (1) rheumatic dilatation of the heart always accompanies pericarditis, (2) rheumatic dilatation of the heart always accompanies endocarditis, (3) rheumatic dilatation of the heart can also occur without pericarditis or endocarditis. It follows that the most frequent early rheumatic cardiac lesion is dilatation of the heart, thus it comes about that this form of dilatation becomes one of the most important events in the history of heart disease. The signs of this dilatation are: (1) slight increase in the rate of the pulse and fall in its tension, (2) feebleness of the cardiac impulse, (3) an increase in the relative cardiac dullness to the left, (4) shortness of the first sound over the impulse, accentuation of the pulmonary second sound at the base, and sometimes a soft systolic murmur at first audible internal to the left fifth space in the nipple line.

I may add in passing that I am a convinced believer that percussion of the deep cardiac dullness in childhood is a remarkably accurate method of investigation. Many students have now passed through my hands, and I have found that they only require some careful instruction to acquire accuracy. I have also learnt that unless they are taught, they think nothing at all of being two inches astray in the transverse size of the heart. Now the bearing of this short digression upon our subject is this—that there is another group of rheumatic cases which commences with a sore throat, possibly enlargement of the cervical glands, fleeting rums, and dilatation of the heart. Some of these cases develop along the lines of the so-called mitral or soldier's heart, the action is tumultuous and irregular, the area of cardiac dullness enlarged, and there are breathlessness, nervousness, and dyspepsia, others develop mitral endocarditis. This group is easily overlooked or not appreciated.

In recent years much has been written upon the danger of undue stress being laid upon cardiac murmurs, and with this teaching I agree and disagree. I agree that when a heart is not functionally affected the mere sound of a murmur need not disturb us, but I disagree if there is a departure from the attitude that a cardiac murmur in a child's heart always requires careful consideration. This murmur may not mean grave trouble, but it is one of our most important signs in rheumatic heart disease, though its presence may only be transient.

There are two obvious difficulties in the supervision of rheumatic heart disease: the first, that when the cardiac infection is the predominant feature, and is not severe, the patient may not come under the doctor's care until there is cardiac disability; the second, that there is a wide difference of opinion as to what constitutes a damaged heart. For this latter difficulty patience and time are essential. We must be prepared to learn from practical experience, from special studies, and from discussions even though these be tinged with intolerance. Eventually steady investigation, no doubt, will determine for us the proper weight we ought to place upon the early signs and symptoms that are associated with the dawn of rheumatic heart disease. But the early stage of heart disease in the young is not an easy subject.

To recapitulate and arrange in a somewhat different order my personal observations upon the onsets of acute rheumatism in the child, these are:

- 1 Fulminating cases, readily recognized as gravely ill
- 2 A large group commencing with sore throat, arthritis, and morbus cordis
- 3 Another large group commencing with chorea and morbus cordis
- 4 A group commencing with chorea only
- 5 A group commencing with heart disease alone, which may take the form of dilatation following sore throat
- 6 A group commencing insidiously, usually with multiple symptoms that remit and exacerbate, thus producing the 'rheumatic state'

I do not presume to think that the experience of one individual can do more than stimulate discussion on this important subject.

I will now briefly touch upon drugs and the prevention of acute rheumatism, and upon the local focus. Some may be horrified to hear that I look upon the routine use of salicylates as an obstacle to our progress. Their value in adult arthritis and for pain I do not dispute, but for years now I have struggled with the worst forms of children's carditis without these drugs. As an example, the x-ray photographs I pass round are from a case of rheumatic carditis with great dilatation and effusion. This child made an excellent recovery and is now thriving, save for a mitral lesion well compensated. No salicylates were given.

I prefer the ethical ester of para-methyl-phenyl anticholinic acid to the salicylates, and have now used it in a good many very severe cases. For myself, I would, in this problem of prevention, rule the salicylates out of the field as a factor, except for the relief of pain.

Next, as to the local focus. I suppose Dr Prime and I were originally responsible for establishing the doctrine of the local focus in rheumatic disease by experiments on tonsillitis, which in turn was suggested to us by the clinical observations of the last generation of physicians. From the first we foresaw its possibilities, and the red-letter day, in more senses than one, that it would prove to be to the throat specialist. It was mortifying to find year after year, the cold acceptance of our theory of infection, but the warm welcome to enucleation of the tonsils in the rheumatic—an operation obviously based for its rationale on that theory.

The subject is a difficult one, going to the very basis of disease, and I must content myself with a series of brief statements:

- 1 I believe the tonsils to be an important site of infection
- 2 I know that skilled enucleation will not prevent a first attack of rheumatism and acute carditis of extreme severity occurring some years later
- 3 I know also that an acute and crippling attack of carditis may directly follow removal of the tonsils in the rheumatic
- 4 I hold that the successful removal of unhealthy tonsils is a valuable prophylactic step if undeterred by exceptions, we view the problem on broad lines
- 5 I believe every case must be considered as an entity, and do not favour routine action
- 6 As to the teeth. I hold that the teeth and gums of the children should be kept as healthy as possible but can trace no clear connexion between acute rheumatism and dental disease in childhood.

In conclusion, our problem to day, as I see it at present, is this: Can we by concerted efforts protect our rheumatic children efficiently, and are we justified in pressing upon the public the great need of their assistance?—for it must be remembered it is, if a rational step, one wholly in their interests. If we do not take an important and serious step of this kind, does this meeting believe that our present methods and remedies are adequate, and can it see at the present any other more promising line of approach? It is, and has been for many years, my belief that such a step, if undertaken earnestly and doggedly, will in due time, but not rapidly, revolutionize the entire subject of the treatment of organic heart disease.

Finally, I must ask you to pardon my dogmatism, for it is the outcome of time limitation and not of character. It was my duty to touch on the salient points of this subject, you, in the discussion, will file down the rough edges and round off this short summary.

II—ROBERT A. ASKINS, M.D. DUB., D.P.H. CAMB., Deputy Medical Officer of Health, Bristol

I do not propose to touch at all upon the many and interesting clinical problems presented by the subject under discussion. Rheumatic infection is, however, a question of urgent concern from the administrative point of view to the public health officer of every large town, and, further, I am convinced that it is one that can be successfully handled only by joint action between the clinician and the medical officers of the State. Fortunately for the community, the day has passed—or nearly passed—when these two branches of our profession looked upon each other with mutual distrust.

For some years we have been paying attention to this problem in the School Medical Department of the City of Bristol, and endeavouring—usually without success—to secure adequate treatment for children suffering from chorea and rheumatic carditis. I believe we are now approaching the day when the term “without success” will no longer apply. In this work we are indebted to the enthusiasm inspired by Dr. Carey Coombs of the Bristol General Hospital, and to the untiring energy shown by him and by Dr. Herapath of the Bristol Royal Infirmary, in investigating the clinical condition of large numbers of cases. Without them this work would not have been possible. We have now reached the time when I feel I am justified in submitting certain conceptions I have formed on the subject.

THE EXTENT OF THE EVIL

I know of no statistics as to this, in either the English or the American literature, which can be regarded as accurate and reliable—chiefly because I believe that many cases included under the heading “organic heart disease” are not correctly so labelled. It is possible, however, to arrive at a rough calculation which will enable us to form an idea of the size of the problem. In 1923, 56,886 people were registered as having died of heart disease—not including diseases of the vessels—in England and Wales. This was one eighth of the total mortality for the year. The fact that a small number of these deaths should in all probability be transferred to other diseases is immaterial so far as our present purpose is concerned. It is estimated by observers of great experience that one-half of the cases of heart disease are of the rheumatic type, the remainder being accounted for by other infections or by the degenerative changes of later life. This is, of course, only a guess, but there is every reason to regard it as a good guess. Further, Dr. Carey Coombs found, in a very careful and prolonged investigation of rheumatic heart disease in Bristol, that two-thirds of the cases commenced between the ages of 5 and 15. If the above data are correct, it means that we are losing 18,962 lives per annum from an infection occurring at the period of school age—a figure far exceeding the total number of deaths contributed by all the commoner zymotic diseases.

Even if we assume that it is an overestimate to credit half the mortality from heart disease to the rheumatic type, and we reduce this figure to one-third, we arrive at 12,640 deaths per annum resulting from an illness commencing during school age. To this we have to add the long periods of illness, the misery of repeated breakdowns, and the immense industrial loss involved during the years which elapse between the time when the patient develops the disease and when he is ultimately killed by it. Surely these are facts of vast importance to those engaged in the administration of preventive medicine in this country.

PREVENTION

At present our knowledge of the etiology of acute rheumatic disease is so limited that we are practically powerless to suggest measures to prevent the infection of the subject by the organism responsible for polyarthritis, chorea, and rheumatic carditis. I would like, however, to submit one or two considerations from the epidemiological point of view.

In the first place, the disease is indisputably due to an organism, whether this be a streptococcus or not.

Secondly, this organism is one of low infectivity, and some special condition is necessary for its successful invasion

—possibly prolonged or massive dosage, as is the case with many other diseases with which we are familiar to-day. Great importance has been attached to various secondary causal factors, such as climatic conditions, damp, poverty, inherited predisposition, etc., while the question of infection, and the prevention of infection, has received less attention. I do not wish to suggest that secondary factors may not be of great importance—for example, only some intrinsic and personal difference will explain the sex incidence of chorea. Also, we know that in other diseases of low infectivity—for example, tubercle—secondary factors are of great importance. I cannot help feeling, however, that ultimate success in preventing the disease may lie in preventing infection, and that prolonged and intimate exposure to infection may possibly be the explanation of the frequency with which acute rheumatic ailments are found in one family, or under conditions of poverty and overcrowding, rather than that this should be accounted for by hereditary predisposition on the one hand, or a mere lowering of resistance due to environment on the other. This side of the problem is, however, at present in the region of romance, and much investigation is necessary before we can tackle the question of infection on scientific lines. Especially must we look to the bacteriologist to disentangle the streptococcal group of organisms, different members of which appear to be associated with such diverse conditions of illness and also of normal health.

REMEDIAL MEASURES

If, however, the limitation of our knowledge prohibits us from adopting measures for preventing invasion of the human body by the causal germ, we can at any rate take steps which are of the greatest value and importance for the early discovery of cases, for curative treatment, for the prevention of recrudescence and of further advance of the disease, and, finally, for rendering those patients who must become cardiac cripples capable of earning their livelihood under conditions most suited to their disability. These steps are not being taken at present, and with a probable loss of some 12,000 to 18,000 lives annually from rheumatic heart disease there is an urgent call for immediate action. Further, in view of the present trend of medicine in this country, there should be no great difficulty in taking what steps are necessary, nor need they be very costly, as I hope to show.

These measures may be grouped under three headings, which I propose to discuss briefly: (1) early ascertainment and diagnosis, (2) treatment, (3) after care, and training of cases permanently crippled.

Early Ascertainment

(a) *The School Medical Service* has splendid opportunities for this purpose. Every elementary school child is medically examined at least three times during its school life. In addition, there are usually arrangements—in towns at any rate—whereby a child can be examined practically at any time at the instance of the parent or school teacher. This latter arrangement is most important for our purpose, but in order that it may be of value in regard to rheumatic disease it is necessary to educate teachers and parents and the public generally in regard to a matter of which they have at present little knowledge. Experience in the case of tuberculosis and infant welfare has already proved the immense good which can be effected by measures of education and propaganda, if wisely and persistently applied. In Bristol we have drawn up a circular couched in simple terms, on the lines suggested by Dr. Poynton. This has been issued to teachers in schools, infant welfare centres, etc., and has been widely circulated, several editions having been exhausted. I can strongly recommend it to anyone wishing to use something of the kind.

In any scheme for ascertainment great attention must be paid to the important class of case which shows no manifestation of rheumatic infection other than a slight carditis that may be producing no outward sign beyond a little vague ill health. By the above means a very large number of cases are brought up for examination. Many of these can be discarded immediately as negative. Those who on a first brief examination show signs indicating a

rheumatic infection must be transferred to our next agency for detailed examination and disposal.

(b) *The Cardiac Clinic*—One must frankly admit that while many cases of cardiac abnormality are perfectly easy to diagnose, there are a very large number of instances in which an accurate opinion as to the presence or absence of organic disease can only be formed after careful and detailed examination at the hands of some specially skilled person. Anyone who goes into the matter will find that many cases have been labelled heart disease which in reality have no organic lesion, and the converse will also be found, though less frequently. In regard to cardiac clinics America is far in advance of us. There are forty-three such clinics in New York alone, and a large number throughout the States generally. The enormous attendance at these clinics proves their utility. Such a clinic may be carried on at an ordinary hospital, in a school clinic, or in some special building. An electro-cardiograph is very valuable, though perhaps not essential. In Bristol we may be said to have at present two such clinics—one at the Bristol General Hospital and one at the Bristol Royal Infirmary, thanks to the zeal of the two honorary members of the staffs of these institutions to whom I have referred above.

Treatment

The next problem is to obtain beds in an open air country hospital school where cases can be sent for prolonged treatment, and where rest is properly balanced by recreation therapy and occupation therapy. Here again America is ahead of us. New York has 392 beds for prolonged treatment of cardiac cases. These patients require great skill in handling, and should be under the eye of a doctor who takes a special interest in cardiology. How can such provision be obtained? At the present day this should not be very difficult. For various reasons, including financial ones, the State is finding it necessary to take over to a considerable extent the treatment of the more chronic diseases among the poorer classes of the community. Local authorities are now making provision for the prolonged treatment under open air conditions in country hospital schools for children suffering from crippling diseases, especially surgical tuberculosis and infantile paralysis. Cardiac disease is essentially a crippling disease. Annexes for the treatment of cardiac cases could very conveniently and economically be added to the open air hospital schools already in existence or being designed. In this connexion it must be borne in mind that by the Education Act of 1921 Parliament has laid upon local authorities the absolute duty of making provision where necessary for the treatment of children attending public elementary schools. We hope shortly to have provision for cardiac cases, on the lines suggested, in Bristol.

After care Vocational Training and Suitable Employment

When the patient has returned from hospital he again comes under the wing of the cardiac clinic, which he should attend for observation and advice as long as necessary. With regard to vocational training, we have for years in our cripple school in Bristol taught suitable trades to a number of cardiac cripples. This could be extended if necessary. Provision could unquestionably be made by voluntary agencies such as the Crippled Children's Society in Bristol, for the extension of such training after 16 years, which is the age limit of a cripple school maintained by a local authority. In conjunction with the Juvenile Branch of the Employment Exchange, such a society could organize the placing of cardiac cripples in suitable employment. The Bristol Branch of the Employment Exchange has already been in correspondence with us on the subject. Schemes on the above lines have been at work in America for a considerable time, and have proved what valuable results can thereby be obtained.

In conclusion, I would like to express my conviction that without setting up a lot of new and elaborate machinery, but by extending at comparatively little cost the means that already exist it would be possible to provide satisfactorily for this devastating disease which is at present so neglected, and I believe that this work should be carried

out by joint action between the clinician and the department of the medical officer of health, and should be closely linked up with the voluntary hospitals, and also with the work of the private practitioner. One fact I think has weighed against the cardiac patient in the past—he is undramatic and suffers in silence, he does not hobble about on crutches, or beg at street corners with paralysed limbs doubled under him. And it is the business of those who work in the wards of hospitals, and those who have to handle death rates, to awaken the public conscience as to the urgency of his needs.

GENERAL DISCUSSION

Dr CURRY COOKE (Bristol) welcomed the evidence afforded by the discussion of a growing collaboration between the administrator and the clinician. The present stage in the campaign against rheumatic heart disease was similar to that which had been reached in the course of the struggle against tuberculosis, at which such collaboration had become absolutely essential to any further progress. This stage was clearly indicated in the title of the present discussion. The possibility of adequate treatment, it was recognized, depended on early diagnosis, and much ingenuity and time were being expended in the search for means of such diagnosis. There might be found in physical signs (physical evidences) or in some biochemical test (chemical evidence) of the body's reaction against rheumatic invasion. But, even if such phenomena were available, it must be recognized that these were evidence that invasion was a *fait accompli*, by which irreparable damage had already been done. Such being the conditions under which they must be content to work for the present, what could be hoped from preventive treatment? He thought it would still be well worth while to make full provision for prolonged hospital treatment of patients with early cardiac rheumatism, so that arrest of the disease might be achieved, even though cure were impossible. A new conception of hospital construction and administration was needed, not only for the treatment of cardiac rheumatism, but also for that of all crippling diseases. Hospitals must provide for long terms of treatment, and such treatment must include open air and occupation. To secure this provision the help of the State medical services would prove indispensable. But the ultimate goal must be prevention, and to this end the clinician needed above all things the help of the administrator, that they might together get to know more of the conditions that predispose to rheumatic infection. Without this further knowledge—which could only be acquired by such a collaboration—any effective campaign of prevention was impossible.

Dr R. H. MILLER (London) said that Dr Poynton had made kind allusion to his opening address on rheumatism given before the Section of Medicine at the Annual Meeting two years ago. Those now present might be interested to hear that the Council of the Association later appointed a subcommittee to study the various rheumatic problems. Its duty was to report on what had been ascertained and done in England and elsewhere, on what of this appeared worthy and acceptable, and on what lines further work was needed. These reports would, he hoped, be available in the next few months. Turning first to the early diagnosis of rheumatism, he would like to emphasize two types of children who were rheumatic though not always recognized as such. The first type was that with symptoms of the "functional" nervous sort—headache, nightmares, sleep walking, recurrent enuresis, and tics. When rheumatism hit the nervous system had chorea followed, but long before that it might produce a condition of nervous instability which might show itself by the symptoms he had enumerated ("latent chorea"). The second type was that often mistaken for early pulmonary tuberculosis. The symptoms were pallor, fatigue, loss of appetite, wasting, and perhaps some shortness of breath, add to these cough due to enlarged tonsils, and the picture of incipient tuberculosis as it occurred in adults was complete. In a child, however, it was frequently due to rheumatism in an early stage. When they turned to the question of the prevention of rheumatism

they saw the importance and significance of the present meeting. For the first time the public health workers were present with the clinicians in their discussion. Two years ago he appealed strongly for help from public health authorities, and to-day they were here. To these workers mainly they looked for an answer to the question of the association between rheumatism and poverty, why it was so common in hospital and so rare in private practice. What was the influence of the environment, the condition of the house, the soil, the locality, the school regime, all these questions were the most important outstanding problems in rheumatism, and it was the part of public health workers to solve them. When trying to trace the influence of the predisposing factors in rheumatism, they should not expect to find them as clearly in cases of chorea as in the non-choreic rheumatic cases, to include cases of chorea would dilute their results. For instance, in considering the influence of diseased tonsils in rheumatic infection, he found that in the last hundred in-patients for rheumatism under his care, 66 per cent showed diseased tonsils, but taking chorea cases only the figure dropped to 56 per cent and in the non-choreic rheumatics rose to 76 per cent. Again, out of 13 cases of rheumatic infection in tonsillectomized children no fewer than 9 were admitted for chorea. He thought, therefore, that they should specially study the non-choreic rheumatic cases so as not to get their results vitiated by the effects of an unknown nervous factor. He was sure that Dr Poynton would expect him to say once more that he was grieved at his view about salicylate therapy. To his mind nothing could be more useless than that the discussion should descend into a pro- and anti-salicylate debate, and so he would merely pass round a temperature chart of a case of acute pericarditis without severe myocarditis which showed, he thought, very clearly the good effects of salicylate treatment.

Dr J A GORRIN (Ministry of Health), dealing with the preventive aspect of the question, advocated proper town planning, the connecting of the whole area of the foundations of houses when built on anything other than a dry soil, avoidance of damp in the house, and of overcrowding both in the home and the school, with proper nutrition, exercise, and sunlight. The school medical service must, he thought, be of immense service in preventing rheumatic infection, and the fully developed school dental service was of equal importance. What additional lines of attack were desirable? First, more knowledge was wanted as to the causal organism. It was still, he said, uncertain whether the streptococcus was the real causal organism. If another organism such as a filter-priser was responsible, it was necessary to know at what stage the streptococcus entered the picture as the important secondary infection. More information was needed as to the route and focus of infection, and a sharper identification of the actual strain of the streptococcus. They wanted observations of the heart by radiological methods right through from the acute stage to perfect restoration, and much more fully detailed study of the etiology of cases and the contacts and circumstances of patients. He would personally like to see acute rheumatism made a compulsorily notifiable disease for five years in three or four counties which showed a high incidence, coupled with the establishment in each area of a complete unit for investigation and research working in conjunction with a suitable home of recovery. He believed that even a considerable expenditure on these lines would be justified when the immense importance of acute rheumatism as a cause of chronic invalidity and death was taken into account.

Dr VINCENT COATES (Bath) said he proposed to deal with the early diagnosis of subacute rheumatic infection in children prior to cardiac involvement, rather than with the fully established conditions of carditis and chorea. If the Section would allow that a combination of the following subjective symptoms went towards the completion of the rheumatic mosaic—namely, headache, stiff neck, sore throat, stitch in the side, stomachache, growing pains, pain behind the knee, nervousness, and irritability, in the absence of other conditions producing a toxic state (and there was no less an authority for this than Dr Still)—then they would

allow that the group of cases to which he was alluding could be regarded as rheumatic, he referred to a large series of children investigated by Dr Thomas, the deputy school medical officer of Bath, and himself, and to a still larger series seen by himself alone. Moreover, that these children were rheumatic was borne out by the results of anti-rheumatic treatment in alleviation of the aforesaid symptoms in the majority and subsequent cardiac or central nervous system lesions in the minority. In considering the rheumatic complex of childhood it was obvious that there were two composite elements, the soil, including heredity, physical make-up of the individual, and environment, and the infection. It was with the latter that he was concerned. Rheumatic infection in childhood was essentially a silent smoulder, and this might never flare into the acute condition of rheumatic fever, but might nevertheless produce irreparable damage to the heart. It was common, however, for acute exacerbations to occur, and one must conceive these exacerbations, be they these affecting the central nervous system, the heart, or the joints, singly or in combination, as following directly upon traumatic causes such as physical fatigue or mental stress, or else upon superimposed infections such as influenza. Was there then any objective physical sign as opposed to subjective symptoms, which distinguished the condition from such diagnoses as "a nervous," "toxic," "difficult," "delicate," "C 3," or "pretuberculous child"? The subcutaneous fibroid nodule, whose presence had been proved by removal and microscopic section, would do this. He did not refer to the larger and often visible subcutaneous node originally described by Sir Thomas Barlow, as occurring in acute rheumatic fever and being indicative of gross cardiac disorder, but to smaller and in some instances almost imperceptible nodules. These could be found in nearly every child who was brought to an out-patient department complaining of rheumatic symptoms, and these children made up about 20 to 25 per cent of medical out-patients in Bath and Bristol under his care. A good deal of practice was required before a definite opinion as to their presence could be confidently ventured. They were most easily palpated over the spinous processes of the vertebral column and along the subcutaneous border of the ulna. If they would allow that the large subcutaneous node of acute disease was the homologue of a cardiac vegetation, and they had the considered opinion of Dr Poynton and Dr Still to this effect if they would allow that the submillimetric nodule occurring in the cardiac muscle was a rheumatic lesion, and they had the work of Aschoff and Carey Coombs to establish this, then they must allow that the subcutaneous fibroid nodule under discussion was not only essentially the same lesion but the homologue of the submillimetric nodule of Aschoff. Moreover, it was a growing conviction on the part of pathologists that this type of reaction—namely, proliferation of the lining endothelium of arterioles and perivascular collections of histiocytes—was a typical response to organisms of the streptococcal group. In view of the almost invariable finding of subcutaneous fibroid nodules in children with a rheumatic history, of the very infrequent finding of these in children without a rheumatic history, in view of the results—namely, disappearance of symptoms and in some cases of the nodules—produced by antirheumatic treatment such as salicylates, alkalis, arsenic, and, in one group, thyroid extract, in view of the fact that a percentage of these children developed carditis or chorea subsequent to the finding of nodules, it was asserted that the presence of these nodules (a) indicated a diagnosis of rheumatic infection, (b) distinguished the rheumatic child from among a large and hitherto undiagnosed group of mildly ill children, (c) indicated the necessity for continuance of treatment in spite of temporary cessation of symptoms. Thus as an early physical sign of rheumatic infection the subcutaneous fibroid nodule gave the opportunity to anticipate cardiac disability to an extent hitherto impossible.*

Dr R E THOMAS (Bath) said that, following on what Dr Coates had said about nodules, he would bring to their notice his clinical experience of their value to the school

* Dr Coates demonstrated a child with these rheumatic nodules after the meeting and microscopical sections of the nodules were shown in the Pathological Museum.

medical officer. In spite of the fact that the existence of the nodules had been proved by excision and examination under the microscope, it took him two or three months' work on selected and unselected, ill and normal children before he was satisfied that the nodules presented a typical clinical, ascertainable variation from the normal. He felt confidence first in palpating the nodules occurring over the spine, especially when they were associated with a feeling of creaking, and it was these that he still considered the easiest to find and the most convincing. When once he had acquired the faculty of using this to him, new physical sign, it proved of astonishing value, for it afforded the clue to the diagnosis of fleeting and suspicious heart bruits indicating those of serious or rheumatic origin. It gave a definite diagnosis in the case of many sleep talkers, sleep walkers, and unstable and nervous children, and it was at present enabling him gradually to label, and he believed label correctly, many of the children included in the large group called 'delicate children' (the anæmic malnourished, plethoric, etc.). The reasons for his confidence were first, the sections of the nodules, and secondly, the results of treatment, which had secured for the children a sufficiently good return to health to gain the marked gratitude of their parents. That Dr Cortes found it necessary for some cases to include in the treatment the giving of thyroid extract or iodine appeared to him to indicate the action of the infection in thyroid insufficiency, and to suggest that one line of prevention might be that of prolonged iodine treatment, especially in early cases selected by the presence of nodules. He had gradually come to regard acute rheumatic fever, chorea, and definite rheumatic illness as a flare-up during the course of a subacute rheumatic infection, and believed that this flare-up was kindled, was determined by some added factor, such as influenza, scarlet fever, a cold, fight, anxiety, or overwork. The subacute infection itself seemed to find dwellers at a low altitude and on a river bed—sub-oil easy victims, but in their cases it was important to note that this disease was not associated with poverty; rather its incidence was chiefly among the bright and intelligent children of skilled and able parents, who were in constant employment, in receipt of good or fair wages, and who were striving, straining, and succeeding in their work and in their social life. The outstanding feature of the subacute infection was its frequency. He quite agreed with Dr Cortes that about 25 out of 100 unselected Bath school children between the ages of 5 and 10 had nodules, and that 20 of these had a definite history of rheumatic symptoms. These figures were as minimal as he could make them, as he felt, and had been warned, that he would not be believed. In partial support of them he would remind the meeting that out of approximately 3,000 children called up for special examination in London during 1922, on account of prolonged absence from school, 23.5 per cent were found to have been absent on account of rheumatic diseases. The reference for this was Sir George Newman's annual report on the Health of the School Child for 1922, which was published in 1923. He pleaded for the finding and treatment of the children threatened by this catastrophe, but not yet permanently damaged, and he knew of no physical sign—no method—except the nodules, which gave a sure enough diagnosis of these early cases as to render practicable the selection and saving of them. He wished to remind the meeting that the full value of this early physical sign would only be available for the public elementary school child when there was the closest co-operation between the school medical officer who discovered and the physician who treated.

Dr A. P. THOMSON (Birmingham) did not go into the question of early diagnosis at any length as that had already been fully considered by previous speakers. He desired, however, to emphasize the fact that frequently the earliest symptom of chorea was a sudden deterioration in a child's school work, and this, he found, was often associated with very marked changes in handwriting. If elementary school teachers could be trained to appreciate these early signs and to refer such children either to the school clinic or to their family doctors the diagnosis of the rheumatic condition would be made sooner in a number of

cases. He had had no experience of the nodules described by Dr Cortes, which occurred with such startling frequency in Bath, but he would certainly examine children in future in the way Dr Cortes suggested. Nodules of the recognized type were very rare in Birmingham. It was clear that the time preventive treatment of rheumatism depended on knowledge of its etiology, and he had recently completed a review of what might be termed the accessory factors favouring infection in a series of nearly a hundred rheumatic children. The family histories showed the incidence of rheumatism in 25 per cent of the cases; this was certainly no greater than the incidence of tuberculosis in the same series, and he consequently did not attach great importance to this factor. A study of the distribution of rheumatism in children in the city of Birmingham showed that the great majority of the cases occurred along the southern banks of the two streams which flowed through the town. Sir John Robertson had kindly arranged for the systematic inspection of the houses of rheumatic children, and from the health visitors' reports it appeared that 45 per cent of them were obviously damp. The orientation, number of windows, and the type of ventilation of the houses did not seem to have the importance of dampness, and in practically all the cases they were said to be clean, and the children concerned were well cared for. This investigation supported the conception that rheumatism was a disease of poor children, but that on the whole it tended to be more frequent among the children of the decent poor than among the squab. It had seemed likely that overcrowding might be a factor of importance in the etiology of chorea, but inquiry showed that there was no more overcrowding in the families of choreic children than there was among those with the other manifestations of rheumatism. Dr Thomson believed that the protection of houses from damp, either by careful selection of the sites or by the provision of better damp courses, and the provision of means for drying children's clothes at elementary schools were important points in prevention. What else could be done? Once the rheumatic infection had occurred, and particularly if the heart were early affected, he quite agreed that provision of accommodation for long convalescence was essential; the most satisfactory type of accommodation would, he thought, he found to be a special hospital school of the type of Baskerville at Birmingham, or like the one to which Dr Paxton had already referred. These school should have close connexion with the existing children's hospitals and with the school medical service. He saw no necessity for the establishment of special cardiac clinics and there was no ground for believing that cardiologists even with the assistance of elaborate electrical appliances were more competent in the care of these cases than ordinary physicians, he hoped very much that the suggestion of specialist clinics would not receive support, for there was in it a very real danger of the isolation of the problem of rheumatism. The results of treatment at a place like Baskerville were encouraging. Of 44 children who had left the school more than a year ago 29 had led the ordinary life of elementary school children, and on examination of these it was found that the physical signs of the heart were either normal or were unchanged since their discharge, all of these cases had signs of definite cardiac on admission. The rather large proportion of unsatisfactory cases was due to the fact that at first a considerable proportion of hopeless cases had been admitted. Finally he wished to say that his investigations showed that the removal of the tonsil from the rheumatic child in some way protected it from cardiac, and he now had tonsillectomy performed when ever it was possible. Of the value of sodium salicylate he was not convinced apart, of course from the treatment of the acute stage of rheumatic infection.

Dr EUSTACE HILL (Durham, President of the Section of Public Medicine) said he welcomed this joint conference between clinicians on the one hand and administrators and others associated with the public health service on the other. He hoped that such arrangements would be extended in other directions, and believed they would make for the mutual co-operation which was so necessary and tend to remove many difficulties and misunderstandings and widen the outlook of both parties. He feared that Dr Thomson,

in criticizing the proposed clinics, did not fully realize the difficulties that existed in county districts and scattered areas. In a large city like Birmingham the children's hospital might well be the centre for examination and treatment, but in a county area he would welcome the association of a cardiac clinic with their orthopaedic scheme. He was afraid that Dr Askins's anticipations were somewhat optimistic, as up to the present few authorities had made provision for cripples of any sort. The Board of Education was, however, pressing this matter, and it was probable that there would be an early increase in such accommodation. He saw no difficulty in the provision of an annex to an institution for cripples for the purpose of cardiac cases. If such provision were made it was essential that the private practitioners should interest themselves in the scheme in order that their patients should benefit by it, and he believed that such a joint conference as the present was valuable, inasmuch as it promoted such co-operation. He considered that Dr Glover's suggestion as to notification was worthy of most serious and careful consideration.

Dr L. A. PARRY (Hove) asked whether "growing pains" were in themselves to be regarded as manifestations of rheumatic infection in all cases.

Dr S. NOY SCOTT (Devon), speaking as a practitioner who was also a medical officer of health, said he thought one of the principal causes of rheumatism in children, at all events in country districts, was to be found in compulsory school attendance. In many such districts children had to walk from one to three miles to reach school, and bad weather was not accepted as an excuse for absence. The result was that children often had to remain in wet clothes and wet boots until they returned home late in the afternoon. The enthusiasm for regularity of attendance on the part of the school authorities was, in his opinion, not due so much to zeal for education as to a desire to obtain the grant which was based on attendance. There was no loss of grant in connection with absence if a medical certificate of unfitness were obtained, but parents were not always willing to pay for such certificates, and he thought the education authority should be empowered to pay for them. This would be one means of preventing many cases of catarrh, tonsillitis, and rheumatism. It was impossible in a scattered population for the school medical officers to do this work. Another probable cause was damp in the houses, and he thought there should be powers to specify the nature of damp-courses so as to ensure adequacy, and to prevent the erection of houses on sites that were damp or otherwise unsuitable. The question of clothing was one which required further investigation. He was not satisfied, for instance, that children whose underclothes were of wool were more immune than others to these infections.

Professor F. L. WYNN (Sheffield), in welcoming the evidence of co-operation between the clinical and administration branches of the profession provided by the discussion, mentioned that, largely through the good offices of the local Division of the Association, a "Medical Advisory Committee" had now been formed in Sheffield, which was representative of every section of the profession—consultants, teachers, research workers, general practitioners, and medical officials. Subcommittees were already investigating questions relating to epidemic encephalitis and cancer, and he hoped this question of rheumatic infection as it affected the city would be taken up at an early date. With regard to the relation of the disease to poverty, he had recently been able to show that certain diseases, such as scarlet fever and diphtheria, were less closely correlated with overcrowding than one would expect, and the correlation was considerably less than that which obtained forty years ago. This was due to the intervention of other factors, especially improved nutrition, and he thought the same would be found to be true of rheumatic infections. He thought a good deal of the time now spent in fulfilling the demands of the Board of Education for routine inspection would be more profitably employed in the careful examination of children reported by teachers, nurses, and others as showing some departure from the normal.

Dr LEONARD LEES (Bristol) agreed that rheumatism was not a poverty disease, but had no doubt of its connexion with enlarged tonsils, defective teeth, and dampness. He had seen comparatively few cases associated with "nodes," and thought the relationship of scarlet fever to rheumatism was a subject that required further elucidation. He was still of opinion that salicylates gave the best results in treatment.

Dr H. SCURFIELD (Sheffield) asked Dr Poynton if his records showed that arthritis was generally absent in cases of rheumatism occurring in children under 5 years of age. He would also like to know what were Dr Poynton's objections to the employment of salicylates and whether he had had any experience in the treatment of cases with the serum of convalescents.

The President (Dr ROBERT HUTCHISON), in summing up the discussion said that there was unanimity as to the seriousness of the rheumatic problem. As a further illustration of it, he would only mention that no fewer than fifty beds in the London Hospital were constantly occupied by cases of acute rheumatism or cardiac disease resulting from it. There was also general agreement as to the necessity for early diagnosis and for the prolonged treatment and supervision of children in whom cardiac disease had developed or was suspected. They were still, however, without much information, though some had been supplied from Birmingham, as to the permanent value of such treatment, and in view of the expense necessarily involved it was desirable that more of such information should be obtained before the profession pressed for the general adoption of such measures. Meanwhile, he was in agreement with those who deprecated the establishment of special cardiac clinics. The discussion had shown that they still had much to learn about the bacteriology of the disease—for all seemed to agree that it was infective—and about the secondary or environmental factors which favoured its development. Dr Reginald Miller had described it as a disease of "poverty." That, however, was a relative term, and perhaps best avoided. Rheumatism was certainly not specially a disease of the slum child, but he entirely agreed with Dr Miller that it was a disease of hospital and not of consulting practice, and he (the speaker) could count on the fingers of one hand the cases of acute rheumatic carditis that he had seen in consultation in the course of twenty-five years. He was inclined to describe rheumatism as a disease of the "elementary school child," but what the factors in the environment of such children which tended to produce it were he was not prepared to say. Dr Noy Scott had enumerated some which might be of importance. He was of opinion, however, that overstrain at school had something to do with the production of chorea in girls. He was certainly convinced that progress in their control of the disease was most likely to come from a careful inquiry into those factors in the environment which appeared to favour infection. Perhaps the committee to which Dr Reginald Miller had referred might be able to furnish valuable information in this respect.

Dr POYNTON, in reply, thanked the Section for the valuable discussion which had followed the reading of his and Dr Askins's papers. This was, he felt so valuable because it was upon broad humanitarian lines. The President, in his wise and careful remarks, came to the heart of the question when he dwelt upon the occurrence of the disease among children of the less well-to-do. Poverty was a complex problem, and he himself was in agreement with those speakers who dwelt upon the tendency of the disease to attack the highly strung, rather fragile children of parents who were striving to better their position in life rather than the more casual and often more needy. Dr Parry's question was one which must inevitably arise, and the answer, he thought, was a study of the individual cases by doctors with a broad outlook—namely, by those in family practice. Pain behind the knees might develop into a severe rheumatism, or pass away rapidly and for ever, the cautious doctor, bearing in mind these alternatives, would go carefully until he saw the turn of events. His reason for not using

salicylates when there was severe arthritis was this. If the drug was specific it needed pushing, and he had found then his results with these delicate children not good and the specificity doubtful. For arthritis prisms all knew its value. He hoped some of them would try tolism, because he thought it more satisfactory in these cases, and it was worth investigating. Many old friends had joined in this discussion, and he thought that there were few points in a short reply which he need dwell upon. A problem which drew into its meshes hospital and general physicians, school medical officers, and medical officers of health, must necessarily lead to differences in outlook, a point he had dwelt upon in the Biddishaw Lecture last year. When these arose the guiding signal was a very clear one, and this was the memory of young and charming children crippled, before 12 years of age, by this grave disease.

Dr ASKINS, replying, remarked that there appeared to be some fear that the institution of cradice clinics would

be taking work away from other agencies. Thus, however, could scarcely be the case, because so far as elementary school children were concerned, practically nothing was being done at present for those suffering from early and acute disease except in a few cases, and under present conditions there was little more that could be done. An essential factor in dealing with this disease was some organized scheme whereby cases would be followed up and kept under skilled observation. Experience had proved that many such children were carrying on an ordinary life during a stage of their illness at which this was of great harm to them. On the other hand, the need for skilled observation was further shown by numerous instances of children who presented a murmur which was not due to heart disease, and who had been wrongly placed under restrictions on the latter supposition. As already stated, cradice clinics could be established at any hospital or school clinic, or wherever was most convenient, provided the above essentials were available.

THE DIAGNOSIS OF LUNG CONDITIONS*

BY

THOMAS M. ALLISON, M.D.,

MAJOR R.A.M.C., T.F. (RET.),

LATE VISITING PHYSICIAN TO THE SANATORIUM FOR TUBERCULOUS CHILDREN STANNINGTON.

I NEED not stress the importance of lung diseases. The deaths, disabament, and debility which follow on lung conditions speak for themselves, and render their diagnosis and treatment of great importance.

THE BREATH SOUNDS

The breath sounds of the child are, in my opinion, the bed-rock of pulmonary diagnosis. The books describe them as puerile—a definition which conveys little—or they say that they are a form of vesicular breathing. In my opinion the normal breath sounds of the child are not vesicular but lingual, and they are therefore harsh in character. They consist of a long harsh inspiration, and a short harsh expiratory murmur. The vesicles are not developed until puberty or for some years afterwards, and vesicular breathing does not appear until that time.

My first point, therefore, is that the normal breath sounds of the child are twofold, are harsh in quality, and are formed in the trachea. At puberty or later they are overlain or hidden by the vesicular element of the adult lung.

The vesicular breathing of the adult (resembling the rustling of leaves in a breeze) is heard normally over the lungs except at the right apex, where the inspiratory and expiratory murmurs of the child may still be heard. The vesicular element is the first to be affected by disease, when the breath sounds of the child again come out. Thus, in emphysema, where the vesicles are destroyed, the condition is characterized by the harsh breathing of the child, but with ratio reversed, the inspiration being short and the expiration prolonged.

The gradations are harsh (normal) in a child, vesicular (normal) in an adult, harsh-vesicular and harsh (abnormal) in an adult, bronchial, tubular, cavernous, and amphoric (abnormal) in both.

ADVENTITIOUS SOUNDS

There is perplexity about adventitious sounds. The rhonchus is the large musical sound heard in bronchitis, while the word "râle," indicating a moist sound, is used indiscriminately. The crepitation is a fine dry sound. The râle, however, may be moist at one time, and in the process of healing may become dry, thus becoming a crepitation. And I would suggest in the place of the râle the term "small sound." This might be contracted to "s-s" and could be described as bubbling, moist, or dry, as the case might be.

There would then be the rhonchus, indicative of bronchitis, small sounds indicative of tuberculous and pus infections, and the crepitation would characterize pneumonia

(and only occasionally pleurisy). The other sounds would be the pleural rub and pleural creaking. To these I would like to add the squeak, a sound which I have observed in the consolidation of tubercle. It is a small rhonchus, and almost as characteristic of tuberculosis as the post-tussive sounds at the apex.

PATHOLOGY OF THE LUNGS

If we consider the morbid conditions affecting (1) the air passages, (2) the lung substance, and (3) the pleural coverings, we obtain the following classification of disease, and I propose as a guide to differential diagnosis to give the characteristic symptom and sign of each condition.

CONDITIONS AFFECTING AIR PASSAGES

Asthma

Symptom Sitting up in bed.
Sign A prolonged wheezy expiration.

Bronchitis

Symptom Cough.

Sign Rhonchus. Wherever there is a rhonchus there is bronchitis. It may be wheezy as in asthma, or sonorous as in chronic bronchitis, but the presence of a rhonchus means an acute, chronic, or superadded bronchitis.

Bronchiectasis

Symptom Postural and profuse expectoration, occasional fever, and occasional haemoptysis.

Sign A creaking rhonchus—indicating a mixture of pleurisy and bronchitis. A dusky face, a barrel-shaped chest, and clubbed fingers complete the picture. Clubbing of fingers, apart from heart disease, is almost typical of bronchiectasis, and is seldom met with in tubercle.

Bronchopneumonia

Acute distress is present. The child is obviously ill, with working ribs, rapid breathing, and some cyanosis.

Signs A mixture of rhonchi and râles—that is, of large musical and small moist sounds. In other words, of bronchitis in the upper, and lobular pneumonia in the lower, lobes.

Broncho-infiltration

I venture to describe this condition as new. It follows measles, whooping cough, pneumonia, and pleurisy, and is present in children and elderly people for years. The chest is kyphotic in type, with apical and suprasternal retraction, moderate expansion, and raised percussion note. The lower lobes are infiltrated by pus organisms, the pneumococcus, etc. These show their presence by post-tussive small sounds in one or both lower lobes. The sounds may be merely marginal or marked râles or crepitations may be present throughout the whole or greater part of the lower lobes. The percussion note over the infiltration is little altered, this distinguishes the condition from tuberculous consolidation. From time to time the infiltration lights up, and rhonchi are present in the upper lobes—hence the name broncho-infiltration.

* From an address on the diagnosis and treatment of lung conditions delivered to the Leeds Branch of the British Medical Association.

Osler characterizes the condition as "marginal crepitations" or as "crepitant rales common at the bases," placing it under chronic bronchitis. But bronchio-infiltration appears to be a distinct condition, and I think its description should be as definite as that of emphysema, infiltrated bases being a constant source of danger.

CONDITIONS AFFECTING THE LUNG SUBSTANCE

Emphysema

Symptom Shortness of breath on exertion

Sign A prolonged harsh expiration. The ratio of expiration to inspiration is often 2 to 1, and thus, together with the barrel-shaped chest and the hyper-resonant percussion note, is distinctive.

Gassing

The effects of gassing are apparently to destroy the vesicles and set up peribronchial fibrosis.

Symptom Shortness of breath on exertion

Signs Here the breath sounds of the child are heard in the adult, with loss of vesicular element, harsh inspiration, and feeble, but not prolonged, expiration. A raised percussion note, not hyper-resonant, and good chest expansion, not diminished as in emphysema, are present. Adventitious sounds are usually absent. The presence of coarse, toneless, interrupted rhonchi is a bad sign.

Fibrosis

Symptom Shortness of breath on exertion, with one-sided chest wall retraction.

Sign Impaired percussion note, feeble breath sounds, and increased vocal fremitus.

Pneumonia

Symptom Rapid breathing ending in a grunt.

Sign Harsh inspiration with fine crepitations, and prolonged bronchial expiration. The picture of pneumonia is one of flushed face, dilated pupils, working ribs, and rapid breathing, whilst the impaired percussion note and the increased vocal fremitus and vocal resonance of consolidated lung are unmistakable.

Tuberculosis

Symptoms Slight haemoptysis, distressing cough, loss of flesh and energy, and evening rise of temperature.

Early Signs (1) Some impairment of the percussion note. (2) Loss of vesicular element, and the tendency of the expiration to become bronchial. Later, the signs of impaired dullness, post-tussive small sounds at the apex, increased vocal resonance and vocal fremitus are easily detected while still later come cavitation and surrounding consolidation which set up cavernous breath sounds, increased vocal resonance and whispering pectoriloquy.

In tuberculous consolidation, especially when healing, the *si si* rhonchus which I would term a *squeal* is often present. It seems almost diagnostic.

Regarding tuberculosis, I think its frequency is sometimes overestimated, and I would place the cases of pleurisy which eventually become tuberculous at 50 to 60 per cent. With regard to tuberculous cervical glands, usually secondary, the percentage is probably not more than 30, the rest being cases of chronic sepsis from oral infection.

In pleuritic or glandular involvement organisms other than those of tubercle should be remembered. And when sending sputum for examination for tubercle bacilli the presence of these other organisms should be asked for. Some authorities rely upon x-ray diagnosis at the hilus. But that these glands may be enlarged by organisms other than the tubercle bacillus should not be forgotten. It is possible that at the hilus the percentage of tuberculosis is overestimated.

CONDITIONS AFFECTING THE PLEURA

If we regard the lung as encased in two paper bags one within the other we gain a rough idea of the pleuritic coverings the opposing sides of which work in harmony in the normal movements of the lung. If they become roughened by inflammation we have pain and discomfort. If they are separated by effusion, pus, or air we have replacement of lung, and, naturally, absence of lung signs and sounds.

Pleurisy

Symptom Pain in the side on coughing.

Signs Occasionally fine crepitations also heard resembling those of pneumonia, but these seem nearer to the ear through the stethoscope. More generally a friction sound is heard, whilst in chronic pleurisy the sound is creaking.

Pleurisy with Effusion—When the pleuritic coverings are separated by a serous (watery) effusion, the fluid gives a flat resisting percussion note, and the lung being absent there is absence of breath sounds, of vocal fremitus, and vocal resonance.

Empyema—Empyema being a purulent effusion, practically the same conditions prevail as in serous effusion.

Pneumothorax—Here the pleura is torn and air replaces the lung, and there is a tympanitic percussion note, with absence of breath sounds, marked collapse of the patient, and marked pain in the affected side. In some cases the breath sounds may be amphoric.

Chronic Pneumothorax—In two cases recently seen of chronic pneumothorax, following tubercle and empyema, both of some years' standing, and in which the diagnosis was confirmed by x-ray pictures, the characteristic sign was a distinctly musical inspiration and expiration. In one case the coin sound was very marked.

New Growths—This is a group apart, and is of rare occurrence, usually secondary to growths in other parts of the body, and need not be dealt with in detail at the present time.

SUMMARY

- 1 The bed-rock of pulmonary diagnosis is the normal breathing of the child.
- 2 The normal breath sounds of the child are harsh, of the adult vesicular.
- 3 The vesicles are not fully developed till puberty or some years afterwards.
- 4 There is more mischief at the base of the lung than at the apex.
- 5 Lung examinations should always include the lower lobes.
- 6 Post-tussive small sounds at the apex indicate tubercle, at the base pus infiltration.
- 7 A doctor should put a bright needle into a dull base, as an unresolved pleurisy may be a missed effusion, and an unresolved pneumonia a missed empyema.

PUERPERAL INSANITY

NOTES OF

CASES TREATED BY INJECTIONS OF OVARIAN EXTRACT (WHOLE GLAND), FROM THE DUFFEE MENTAL HOSPITAL, WESTGREEN.

BY

E. A. WILSON, M.D., AND T. CHRISTIE, M.B., CH.B.,
LATE ASSISTANT MEDICAL OFFICER ASSISTANT MEDICAL OFFICER

I.—By DR. WILSON.

The following cases are recorded to illustrate the value of the hypodermic injection of ovarian extract in puerperal insanity and possibly in other forms of acute confusional insanity. It probably acts by bringing about the re-establishment of menstruation.

CASE I.

Mrs. A, aged 25, was delivered of her first child in January 1922 and within a week developed acute confusional insanity. This continued until she was admitted to Westgreen Mental Hospital six months later in an emaciated state. She remained in a condition of acute mania for the next twelve months, during which time she had calmer periods and gained weight but only to lose ground again. There was no menstruation. At the end of the nineteenth month a hypodermic injection of extract of ovary corresponding to 30 grains of fresh gland was given, and at intervals of from four to nine days successive injections amounting to eight in all. From the first injection improvement was seen, and within six weeks she was up and going about, rational, interested in her surroundings, sleeping well and eating well. Menstruation began again, and in the twenty-third month since her breakdown she was discharged home as cured. She has since undertaken her regular household duties with success, and has undergone another pregnancy with no trouble.

CASE II.

Miss B, aged 22, gave birth to a child in June 1922 and ten days later she broke down. She was admitted immediately as a typical case of acute puerperal insanity. During the first three months of her illness her mental state was unchanged and there was no menstruation. The extract of the ovary was given

hypodermically and then replaced by corpus luteum given by the mouth, it was continued for two months. She menstruated for the first time within a month of the administration of ovarian extract, and this coincided with improvement mentally. She was discharged home cured in the seventh month after she broke down.

CASE III

Mrs C. aged 24 was admitted in October, 1923 with five months' history of mental breakdown following on the birth of a first child in May. She was in a stuporose condition, confused, and took no interest in her surroundings. She was observed for a week and there was no change. Eight injections were given at intervals of up to seven days, and at the end of that time she was up and going about sociable, and able to tell us about herself. She was discharged as recovered on January 12th 1924. I have no notes regarding her menstruation as I was not then fully alive to the importance of that function in this connexion.

CASE IV

Mrs D. aged 40 admitted in June, 1923 was restless, agitated, almost violent, and incoherent. There was history of ten months' mental hospital treatment in 1919. The child which was not her first, was born in the summer of 1921, since then she had never been well but no actual mental breakdown occurred until five months afterwards, when she lost control, but was not sent to hospital. She got better, but broke down again in the summer, 1923. It was noted that on admission the mammae were lactating, and a vaginal discharge was present, which cleared up on douching. In September and October a course of thirteen injections was given. Improvement was marked, she put on weight and was discharged in January, 1924. Menstruation had begun again before she left.

CASE V

Miss E. aged 32 was admitted in December, 1922, in a state of chronic mania. There was no history of pregnancy and no stricture gravidarum. She had to be fed by tube for a time. She would hurdle over beds, tables, and chairs and was very strong for her small physique. There was no change during eight months. The first injection of ovarian extract made her sleep like a log for thirty hours during which time she hardly moved nor had she any nutriment. This was in contrast to her usual extreme restlessness and insomnia, which even hyosine failed to control. Twelve injections were given in nine weeks. She menstruated within a week of the first injection the first since she was admitted. In three months she gained 21 lb in weight. Improvement was marked and she became a useful member of the hospital laundry staff. She was discharged to the care of a relative in February, 1924. For over a year now she has been in service and keeps well.

I include this last case with the others because it is similar to puerperal insanity, and, I think, must be considered along with it. Criticism of the above cases will be directed to the fact that puerperal insanity often spontaneously clears up within nine months of its onset. Many authorities stress the point that sanity returns with the return of menstruation. The first case gives an uninterrupted period of nineteen months' mania, which cleared up with the return of menstruation. The rationale of giving ovarian extract (I write now with the advantage of two years' theorizing subsequent to the experiment) depends on its undoubted action as a promoter of menstruation. Granted that the administration of the injections may have coincided with a spontaneous recovery, especially in those cases with a short history, I would yet maintain, especially from Cases I and V, that the ovarian extract was the deciding factor. From a general survey of these cases and of others I would advance the following suggestions:

1 If the patient can be got to menstruate her difficulties are over.

2 This can be done by giving ovarian extract in sufficient quantity straight into the blood, as nature gives it.

3 The mental breakdown is due to a temporary deficiency in ovarian secretion, a deficiency which can be made up.

In conclusion, I should like to ask a question. The extract was given to other patients of different types experimentally. It had the effect of stimulating obesity. Are there any data available giving in figures the effect of ovarian extract on basal metabolism, in contradistinction to the action of thyroid?

II—By DR T. CHRISTIE

I heartily concur with the observations made by Dr Wilson on the treatment with ovarian extract of patients suffering from acute confusional insanity where pregnancy is the exciting factor. In my experience, however, I have found that these patients stand very well more intensive treatment than he advises. My method is as follows: For the first week a dose corresponding to 30 grains of fresh gland is given three daily, for the second week twice daily, for the third week once daily, and thereafter every

third day until the onset of menstruation, then once weekly till the next menstrual period.

I have also found ovarian extract useful in cases of confusional insanity coming on at the climacteric period. In these cases I have found the above dose every second day of great benefit—I record an example below. In two cases I have noticed signs of a toxic effect. The outstanding symptoms were a macular rash, chiefly over the chest, abdomen, and arms, inclination to become comatose, obstinate constipation, and in one case vomiting. Free purgation and cessation of administration saw both patients well in a week, and resumption of treatment saw no recurrence of toxic signs.

Case of Acute Confusional Insanity with Pregnancy the
Exciting Factor

Mrs W., aged 28. Mental symptoms had begun four days after the birth of her child, she was admitted to the poorhouse, and stayed there one month. After a fortnight at home she was readmitted there, she came eventually under my care in the tenth week of her illness. She was moderately well nourished. Mentally she was confused, lacked cerebral control, was shouting and singing, and unable to sustain a simple conversation. She had no memory, she refused food, and slept poorly. Intensive ovarian treatment was begun on the fourth day after admission and within four days she was sleeping well. Three days later the restlessness diminished and soon she was taking her food herself. During the month that followed her mental condition varied: sometimes she was noisy and confused at other times quiet and rational. The spells of confusion became less and occurred at greater intervals, she gained weight and slept naturally. After two months' treatment she began to menstruate, and a remarkable change was noticed within four days from its onset. She became quiet and behaved in a rational manner and her memory returned. She was discharged cured.

Onset of Menopause the Exciting Factor

Mrs F., aged 56. From the history received it was gathered that the menopause began about three and a half years before admission. She was stated to be light-headed, extremely talkative, asking senseless questions, and being sometimes delirious, at others stuporose. On admission she was depressed and stuporose and incoherent, and was treated on general principles. It was noticed after a time that she had spells of confusion at regular intervals. She would be acutely confused for about a week then apparently recover and act in every way as a rational woman, taking an interest in everything and working well. Her spells of mental confusion occurred regularly every three weeks and inquiry elicited the fact that her menstrual periods had been at intervals of twenty-one days. One week before the next attack was due I gave her an injection every second day. She never had another attack, as I anticipated when each spell was due. And so for three spells. Then I omitted injection for two spells and she was discharged. No further attacks have been recorded.

We are indebted to Dr William Turch-Mackenzie, the superintendent of Dundee Mental Hospital, for permission to publish these notes.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

POISONING BY COPPER SALTS IN BREAD

I was recently called to see a boy who had had a severe attack of vomiting followed by pyrexia. His mother showed me portions of a loaf of bread, in the centre of which was an irregular area of a light green colour about an inch in diameter. This, at first sight, I took to be "mould," but on further examination small fine metallic particles could be seen.

The loaf was bought from a high-class bakery where the bread is made by machinery, and delivered wrapped in damp-proof paper. It was bought on Saturday and cut on Sunday, the green colour being immediately noticed. As it was the only white bread in the house, it was cut down until no further green colour (which was thought to be "mould") could be seen, and the remaining portion was then partaken of by all the members of the family.

The boy, aged 5 years, the youngest member of the family, became violently sick two hours afterwards when in bed and asleep. He vomited twice during the night complained of discomfort in the stomach but had no severe abdominal pain. He suffers from habitual constipation, and had no diarrhoea. He was very sick again the next day and became feverish, his temperature rising to 103° on the following day. When seen by me he was pale and had a furred tongue but his temperature had fallen to 97°, and he had no signs of any severe abdominal condition. He was well in a few days.

The boy's father stated that after eating the bread at tea time he did not feel any ill effects immediately, but did not want any supper. He had no vomiting but diarrhoea began about noon on the following day, continued the next day, became very severe

(about twenty times) on the third day, subsiding under treatment the following day. He had no acute abdominal pain but complained of a dead feeling in the stomach. He had pruritus in his joints, particularly in the knees and ankles, elbows and wrists. He also was well in a few days.

The mother had diarrhoea but no vomiting. She ate very little of the bread and the ill effects were less pronounced.

A son aged 9 years came home from school at noon on the following day, crying with pain in the abdomen, which was relieved after an action of the bowels. He had no vomiting but frequent motions for two days.

Another boy, aged 12 years, who came to tea with his cousin on the Sunday, had similar symptoms.

Finally the dog, which had some of the bread mixed with his food, was evidently in pain, and had diarrhoea for two days.

At my request samples of the bread were submitted by the father to the research chemist and metallurgist at the works where he is employed. The report sent to me states that the given colouring matter was undoubtedly due to copper salts, resulting from the action of the products of fermentation, during the baking of the bread, on the particles of the metal seen in the loaf. During the process of fermentation carbonic acid and acetic acid are produced, and these, acting on the particles of copper, form (1) basic copper carbonate, and (2) basic copper acetate (verdigris).

A visit was then made to the bakery to determine how the copper particles got into the bread. It was found that the flour was carried from one building to another by a "conveyor" which, owing to the distance, was in two sections. At the junction of these two sections was a "bronze bearing," and it is highly probable that when this bearing became hot from lack of grease at any time, the grinding of the dry metallic surfaces produced fine particles of bronze, which became mixed with the flour, and were carried on to the mixing machine.

Considering the small amount of bread eaten, the symptoms produced were sufficiently alarming. There was evidently more copper in the loaf than it first met the eye, for after being kept for a few days, and dry, the greater part of one slice became light green in colour.

It is obviously of importance that if a bearing is necessary in a machine used in the baking of bread, it should be made of some metal not acted on by the products of fermentation during baking.

PREGNANCY AFTER THREADING BOTH FALLOPIAN TUBES WITH CATGUT

The following notes may be of interest to those who have not yet performed this operation.

A woman, aged 24, married in November, 1920, aborted early in 1921 and was attended by a "handy woman" after that she complained of constant backache and dysmenorrhoea.

To cure this condition I opened her abdomen in February 1924, at Hopefield Cottage Hospital, Portluth. The uterus was retroverted and adherent; both tubes were twisted and were held by adhesions in Douglas's cul-de-sac. The uterus and tubes were liberated, and an effort was made to force air through the latter by means of a syringe placed in their fibrinated extremities. This manipulation showed that both tubes were occluded. A long fine piano wire probe, fixed at one end and passed down one tube until its further progress was arrested within a couple of inches of the uterus. At this point the tube was divided and a portion of the uterine end resected. This procedure enabled me to pass the probe through the remaining portion of the tube and into the cavity of the uterus. The probe was now threaded with chromicized catgut; its point was forced through the anterior wall of the uterus and withdrawn, bringing the catgut out with it. The needle was removed and a knot placed on the catgut to prevent it slipping back. The portion which protruded through the Fallopian opening was again threaded, and by means of the needle was made to pierce the ovary. After the latter had been brought into proximity with the tube, a further knot was placed on the catgut where it emerged. The divided ends of the tube were now stitched together round the central catgut core. The Fallopian probe was made to pass with some difficulty through the other tube. The probe was brought through the wall of the uterus, and the catgut which it carried was knotted in two places as before. The uterus was then fastened to the lower peritoneum by two fine silk sutures; the vermiform appendix was removed, and the abdomen closed in the old way.

The patient made an uninterrupted recovery, has been cured of all pain, and was safely delivered by me of a normal and living female child on July 22nd 1925.

In performing this operation I closely followed Professor Trendelenburg's technique, which I had observed while acting as his resident in Dr. Steevens's Hospital, Dublin. It is sometimes very difficult or impossible to pass the probe through the interstitial portion of the tube. To do so it may be

necessary to cut the tube flush with the cornu of the uterus, and then gradually dilate it by employing fine wire (as used for clearing rectylene lamp burners) in the first instance, the calibre is gradually increased by the employment of ordinary sewing needles of different sizes.

Portluth.

Reports of Societies.

BRITISH ORTHOPAEDIC ASSOCIATION

The meeting of the British Orthopaedic Association held at the University Medical School, Manchester, at the end of last week (October 23rd and 24th) was well attended, and in every respect most successful. Mr. Fairbank was elected President and Sir Robert Jones was elected to the newly created position of Emeritus President. The following is an abstract of his valedictory address at the termination of his tenure of office as president.

THE TRAINING AND ACTIVITIES OF THE ORTHOPAEDIC SURGEON

SIR ROBERT JONES began by thanking the association for the honour it had done him in asking him to preside over it for the last six years. The branch of surgery the members practised had, he said, made very encouraging progress since the war. It was now generally recognized that no single man was sufficiently experienced to deal safely with every department of general surgery. Speaking in general terms, they devoted their energies as a body to the surgery of the spine and extremities, and also to certain specialties affecting the arms and limbs. This of necessity comprised a very large section of general surgery, and if their work was to be progressive it demanded that they should undergo a thorough training in the other branches of general surgery. The problems met with in the war could only be solved by those whose training embraced a sound knowledge of the fundamental principles of general surgery. Orthopaedic surgery of the future would demand a no less efficient standard, and for this reason attention should be directed to the adequate training and equipment of their successors. When he looked back upon his own life he sometimes reflected what he would do if his surgical career were beginning afresh. Of one thing he was quite sure—he would select the surgery of joints and bones as his future field of activities. He would therefore endeavour to make his education sufficiently comprehensive to enable him to appreciate the scientific basis of any new advance, and he would pay a specialized attention to anatomy and physiology. With this end in view he would try to obtain a post in the anatomy rooms. He would also make a point of striving for the highest surgical qualification. Nothing, he said, had served him so well as his experience as a general surgeon. A very close relationship existed between neurology and their own work, and he strongly urged all young surgeons, about to take up orthopaedic work, to acquire familiar knowledge with the chief types of neurological disease. His advice was not to specialize too early. Facility in operative technique was best attained in youth.

If a surgeon could obtain an orthopaedic post after a few years in general surgery he was fortunate. If there was no orthopaedic department he could become full surgeon and work chiefly on the spine and extremities. As soon as possible after qualification he should endeavour to travel, not necessarily abroad. A surgeon, whether young or old, who ceased to imbibe information should be put aside to rest; his activities would never be missed. When the time arrived to specialize, Sir Robert said, he would endeavour to become attached to a county open-air hospital in a visiting capacity. To keep abreast of modern surgical literature should be almost an obsession. And the writings of the ancients should not be neglected. If he had been well acquainted with the works of Hippocrates he would have known that the treatment of club-foot two thousand years ago differed very little from his own, and that open air wards—very much on the lines of the Heswall Hospital—were attached to the Temple of Aesculapius. Such knowledge was a useful check to the arrogant spirit.

Another and perhaps even more important aspect than the equipment of the orthopaedic surgeon was the training of the student. This was rendered much easier because during the last few years many of the medical schools had realized the need for giving more attention to this important field of surgery. They should fully realize that orthopaedics was a considerable branch of general surgery. It was as distinctive a branch as that of the abdomen. The abdominal surgeon, the neurologist, and the orthopaedic surgeon were all branches of the general surgical trunk. If, at a low estimate, the surgery of the spine and extremities occupied a third of the whole field of surgery, it followed that there should be a proportionate bed accommodation for cases requiring ward treatment. Whether the cases or the surgeons were called orthopaedic or not it made no difference. The surgeon at the head of such a department of general surgery should obviously have adequate staff rank, and be allowed his share in the executive control of the student's time. If the general hospital to which he was attached had already a recognized orthopaedic unit in charge of a full surgeon, the young surgeon should act as assistant surgeon both to the special unit and to a general surgical unit. The next period should be one of pure specialization, and the surgeon's activities should be devoted to orthopaedic surgery. In this case the assistant surgeon would take the title of orthopaedic surgeon to the hospital, and be awarded the status of a full general surgeon.

Once an orthopaedic unit was established it must take its share in teaching. As representing a department of general surgery this unit must be responsible for teaching students the surgery of the spine and limbs. The lectures and demonstrations of the orthopaedic surgeon should not be looked upon as a special course any more than the lectures on the thorax, brain, or abdomen. The less the subject was made a separate specialty from the student's point of view the better. He should come to know that on certain days in the out-patient department he was better and more clearly instructed on the prevention and cure of deformity. If the teaching was good it would become sought after. There seemed but little opportunity offered to the post-graduate who desired a course of systematic training and yet what need there was for it! The Royal National Orthopaedic Hospital, with its wealth of material and representative staff, should be able to supply this need in London and the southern counties, and Oxford, Shropshire, and Birmingham should be available for other districts.

Progress during recent years was well illustrated both in the creation of new orthopaedic departments in many general hospitals, and the opening of open air hospitals or annexes in various parts of the country. Under the guidance of the surgeon physiotherapy was placed in a proper perspective, and was not allowed to run rampant along blind alleys. Interest in the preventive side of the cripple problem had resulted in a strong public desire to help in a campaign which bade fair to become truly national. The time was not very far distant when every crippled child would have the advantage of education and skilled treatment in fresh air and sunlight. For many years most of them had known of the close relationship between fresh air, sunshine, food, and rickets, but now, owing to the researches of Mellanby, Chick, Leonard Hill, and others, this relationship was explained and placed on a scientific basis. The State was supplied already with sufficient data to eradicate the disease, and they should take every opportunity of impressing upon local authorities their grave responsibilities, so that the out-patient departments should be freed from rachitic deformities.

The pathetic plight of the adult cripple should not be forgotten. If a cripple had passed the age of 14 it was next to impossible to offer him adequate help. As surgeons they had the desire and the knowledge, but they lacked the opportunity. It was true that certain hospitals, such as the National Orthopaedic, the Shropshire Orthopaedic, and the Wingfield Hospitals, undertook the treatment of the adult, but there were vast districts in the country which offered no facilities of any kind. The adult cripple of to-day must seek admission in the wards of a general hospital, and they knew that, without questioning the

capacity of any surgical staff to handle far advanced orthopaedic cases, as in the case of a child, there was no accommodation there for patients requiring several months of continuous treatment—nor was there any provision for after care. He was evacuated from hospital before he was cured in order to accommodate an urgent case, and apart from an occasional visit from the district nurse he was completely cut off from medical supervision. As an association of surgeons they should do their utmost to mitigate the tragedy of the adult cripple by securing for him adequate treatment, educative facilities, and help to employment. In the dismantling of Poor Law infirmaries, which was under immediate contemplation, there was a gleam of hope. Many of these could be equipped to deal with this problem in proportion to its urgency and gravity.

One great advantage of the campaign which was being waged on behalf of the cripple was the dissemination of a knowledge of the laws of health amongst the poor and partially educated. Ignorance of the laws of health, however, was surprisingly apparent amongst the rich and educated. We are all, said Sir Robert, proud of our public schools. In many respects they are unequalled in any other country. In early days schools like castles were erected on water, often in damp, marshy places. They were confined in space, ill lighted, ill ventilated, with small insanitary studies, low ceilings, and the inmates fed on rough, unvaried food. These were the practical relations of invention to necessity. All schools should be in dry and sunny places, facing south, with access to air and sunlight. He looked forward to the time when public school boys would sleep in the open air, and, when possible, be taught in the open air. It should be imperative that the supply of milk be of guided purity and free from tubercle. His criticism was happily by no means universally applicable, but the spirit of age hung tragically over certain of the schools, and the fact must be grasped that the laws of health were unconsciously opposed to the medieval tradition.

In conclusion Sir Robert Jones said: "These are only a few of many kindred subjects which I hope will continue to engage the activities of the orthopaedic surgeon. Let us realize our part in modern civilization and the future of our race. Recovery from disease has no longer become our sole ambition and object. That middle distance of our calling is receding on the horizon, and the prevention of grave disorders and impoverished vitality is the new and supreme ideal of natural happiness and well-being."

SCARLET FEVER IN BOARDING-SCHOOLS

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on October 23rd, the President, Dr. JOHN McVAIL, in the chair, Dr. T. STICER WILSON read a paper on the management of scarlatinal epidemics in boarding schools.

Dr. Wilson, having commented on the extreme difficulty of diagnosis in mild cases, expressed the opinion that, in institutions, a careful search for and isolation of desquamating children was an important measure. He described, illustrating his remarks with a series of excellent photographs, various types of desquamation. In his opinion the appearance of circular areas of desquamation, increasing in size and number from day to day, and then location at lines of juncture of thick and thinner epidermis, were important points. He remarked that the soddenness consequent on frequent washing of the feet when periodic examinations were made sometimes led to difficulties in diagnosis.

Dr. E. W. GOODALL, in opening the discussion, expressed himself as somewhat sceptical of the value of desquamation for diagnostic purposes. In his opinion there was no reason to believe that infection was conveyed by desquamated particles.

In the subsequent discussion, which was carried on by Drs. F. M. TURNER, J. G. FORBES, Sir JOHN BROADBENT, Drs. R. A. O'BRIEN, S. MONCKTON COPEMAN, Major GREENWOOD, T. CARNWATH, and the President, it was generally agreed that the most hopeful prospect of controlling epidemics of scarlet fever in institutions was afforded by developments along the lines of the Dicks' work. Dr. Wilson replied.

Reviews.

PATHOLOGY OF THE EYE

IN English ophthalmic literature there are two standard books on pathology—the one, the four-volume, classical, and uniquely comprehensive work of Sir John Parsons, and the other the smaller textbook of Mr. TRAUFER COLLINS and Mr. MAYOU. The former, published from 1904 to 1908, has never been re-edited, and is now, we believe, out of print, the latter, originally produced thirteen years ago is one of a series of volumes constituting, under American auspices, an international system of ophthalmic practice, has now appeared in its second edition as a separate and independent work, under the title of *Pathology and Bacteriology of the Eye*.¹ With the growth of knowledge and the revision of opinions that have taken place since its first appearance—in which progress the authors have taken no small part—the new edition is to all intents and purposes a new book, far outdistancing its predecessor in size and in value.

Holding that pathology is disordered physiology, the authors have discarded the time-honoured classification of diseases on an anatomical basis, and, as in the first edition, have adopted a physiological classification, tiering of the various morbid conditions by dividing them into generalized functional categories, each embracing the entire eye. Any system of classification must savour of artificiality on occasion, and the authors themselves have compared the process to the working out of a jigsaw puzzle, the construction of whose general framework is easy, but in which the chief difficulty arises in fitting in the central pieces to make a complete picture. The difficulty may be exemplified in that, under the same subsection entitled "Disturbances of the circulation and constitution of the blood," we have grouped together conditions so far apart as diabetic retinitis and exophthalmic goitre, xerosis of the conjunctiva, and tobacco amblyopia, while this can be logically justified, it leaves the reader at times with a certain sense of topsyturvydom. The great disadvantage of the customary system is the amount of overlapping it necessarily entails, that of the one here introduced is the difficulty the reader sometimes finds in laying his finger quickly on what he wants and of following out the various dyscrasias of a tissue without searching through every chapter of the volume. This arrangement is novel, and, like all others, has its disadvantages, but it is interesting. In its general co-ordination, and in its acknowledgement of the precedence of function over structure, of physiology over anatomy, it is scientifically sound, in its application to particulars the authors have shown no little ingenuity, although everyone would not care to accept all the details.

The first chapter deals with the various aberrations that occur in the development of the eye, arranged systematically on an embryological basis, the second with aberrations of growth that occur as neoplasms after the state of maturity has been reached. These form excellent and concise treatises on classical and orthodox lines. The third chapter, which considers disturbances in the circulation and constitution of the blood, embraces a great variety of conditions, all presented in an interesting manner. Reference should especially be made to the treatment of the disturbances in the circulation of lymph, and to the hitherto somewhat neglected subject of decreased intraocular tension. There follows a chapter on injuries—mechanical, chemical, thermal, electrical, and radiant. The fifth chapter deals with inflammation, the general reaction of the process and the general reaction to it, the modifications of these general principles as they reveal themselves in the several structures of the eye, and the methods of infection and of dissemination of infection in ocular disease, it is followed by a very detailed, and yet concise, account of the bacteriology and parasitology. The concluding chapter is on degenerations, and there is appended a useful practical guide to laboratory methods.

¹ *Pathology and Bacteriology of the Eye*. By E. Trauffer Collins F.R.C.S. and M. S. Mayou F.R.C.S. Second edition. London: Williams Heinemann 1925. (Med 8vo pp xxviii + 731. 366 figures 4 coloured plates 42. net.)

As has been said, the work is to-day the standard textbook on its subject. It is well worthy to occupy that position, but this fact entails no little responsibility on the authors and some also on the reviewer. A book holding such a position must be able to withstand criticism, and the authors should not, we feel sure they will not, resent suggestions for its improvement. Its main fault is that it is rather more personal than representative. Two examples may be mentioned. Retinitis pigmentosa is described as a typical idiopathy of the neural elements of the retina, and no mention is made of any other theory of its pathogenesis. We are not at all sure that this view is universally accepted as final among ophthalmologists either at home or abroad. In a monograph this section would be rightly considered an able exposition of the authors' views, which may well be correct, but this book is more than that. With its wider scope and greater responsibility, with its potential public primarily the student of ophthalmology and the practitioner taking up this branch of medicine as a specialty, its value from these points of view would have been enhanced had mention been made, no matter how critically, of the other views that are held on this question. Again, the authors state with certainty that the aqueous is a secretion, that is accepted and dismissed as an unconditioned and unquestionable fact. Here too, we think, the same observations hold good, and that for the benefit of the student, at any rate, who is starting from the beginning of things, the other side of the question was deserving at least of mention.

References to literature are purposely curtailed, and while English authorities are largely quoted foreign literature is rarely mentioned. The findings of slit-lamp microscopy are referred to on a few occasions, but the authors have probably been wise to refrain from a systematic appeal to a method of investigation still in its infancy, whose results still require much correlation with the histological characters of diseased conditions before they can be incorporated usefully or safely in a work of the character of the present.

The book is large and well finished, but unnecessarily heavy, perhaps, owing to the nature of the paper. The illustrations throughout are of high standard, and are lavishly provided, and there are few printer's errors.

OSLER AND McCRAE'S "MEDICINE"

THE famous *Principles and Practice of Medicine*, first written in 1892 by the late Sir WILLIAM OSLER, is now in its tenth edition, and is the second solely revised by Professor THOMAS McCRAE. In the preface light is thrown on the original author's almost conservative error in making additions, and his dictum in this connexion, "a textbook is not a yearbook," is aptly quoted to show that before new matter is admitted it should be well established. While many judicious additions have as usual been made, the volume is very little bigger than the last edition, and Professor McCRAE, than whom no one is better fitted to do so, has retained the personal and historical touches, and as far as possible the *ipsissima verba* of the beloved teacher.

Besides the thirty-one subjects mentioned in the preface as new or altered, many changes have been made in the account of angina pectoris the late Sir Clifford Allbutt's explanation, that the pain is in a large proportion of the cases (about 90 per cent.) due to disease of the first part of the aorta, the coronary arteries and myocardium having little or nothing to do with it, though highly responsible for the mortality, is now regarded as the most satisfactory, the surgical treatment is advocated by Jounesco and Wenckebach is described. New tests, such as the Dick test for immunity in scarlet fever and the Hymans van den Bergh reaction, receive due notice, and the section on jaundice is now based on Dr. J. W. McVee's classification. The lapse of five years has necessitated some modifications in the arrangement of the diseases, thus scarlet fever and rat-bite fever have been transferred from infectious diseases of

The Principles and Practice of Medicine. Designed for the use of Practitioners and Students of Medicine, originally written by the late Sir William Osler Bt MD FRS (tenth edition thoroughly revised by Thomas McCrae MD London and New York D Appleton and Co 1925 (Med 8vo, pp xxviii + 1233 23 figures 16 charts 30s net.)

of the air and its small cooling and evaporative power, and is not due to any chemical contamination. In order to estimate the cooling and evaporative powers of the air the kata-thermometer, which is described in considerable detail, was invented, and has been found to be useful in determining the velocity of the movement of air in rooms, factories, schools, shops, and mines.

The influence of surrounding conditions, such as those of town and country, and of tropical climates is considered and illustrated by statistical tables of mortality rates. Special chapters are devoted to clothes, colds, light, food, and metabolism, in connexion with vitamins it is suggested that white flour should be treated so as to induce a proper use of finely ground wholemeal or natural flour in bread. This clearly written monograph is full of valuable information and contains much wise advice for personal hygiene.

THE UNCONSCIOUS

Dr A HESNARD, a well known French psychiatrist, has contributed to the *Encyclopédie Scientifique* a valuable little volume entitled *L'Inconscient*.¹ It has been his aim to show that consciousness is not the essence of life and mind, and that the behaviour of individuals is determined by psychic or living processes of which the subject is unaware and which are not discoverable by introspection. The term "unconscious" is here used in the widest sense to include all psychic phenomena, both inherent and acquired, which lie outside the field of awareness, it is not, as the author holds, an "entity," but the primary quality of a vast number of psychic activities collected together by objective methods of investigation.

The subject is considered from the standpoint of both general and abnormal psychology, and in a condensed form the author has succeeded in conveying a great deal of information. Included in this volume is a critical discussion of the theories of the unconscious which have been formulated by philosophers, psychologists, and clinicians. With admirable restraint, however, the author himself adheres strictly to facts, and refrains from proposing a new theory. Though this modest essay, as Dr Hesnard describes it, only deals with the subject on broad lines, the psychopathologist will find it most informing and useful. Especially valuable is the section dealing with the psychology of the psychoses, where the connexion between organic disturbances (toxic conditions, etc.) and their conscious expression in symbolic delusional states is clearly traced. The volume contains a lengthy bibliography, and is well indexed.

MALE INFIBULATION

The word "infibulation," according to the *Concise Oxford Dictionary*, means "fastening of sexual organs with clasp to prevent copulation." The unabridged dictionary adds little of importance to this definition. The practice of male infibulation is described by Celsus. It consisted in passing the pin of a brooch or safety-pin or else a ring through the prepuce in front of the glans penis and thus producing an artificial phimosis. It was thought by the Romans and others that by preventing sexual intercourse at and after the onset of puberty, in boys, their voices could be prevented from breaking. Hence this practice. In the eighteenth and nineteenth centuries it seems to have been revived or at least recommended as a preventive of masturbation. All this may be learnt from Mr ERIC DINGWALL's book on *Male Infibulation*,² in which he sets forth the fruits of an inquiry into this subject, on which he has expended a great amount of erudition and industry. In the later part of the book he deals with what he calls the Greek form of infibulation, which is wrongly so called, as it consisted in tying up the prepuce and slinging the organ, it was practised by athletes and others. He also devotes a chapter to phallus curvatus, illustrated by drawings from Greek vases, in which he puts forward the view that curvature of the

penis is a sign of excessive venery. His knowledge of medicine apparently does not include the condition known as chordee. There is also in this book an account of the methods in vogue among savages of covering the penis by a case or sheath in lieu of a loin-cloth. Such a sheath was described by Lionel Wafer as used by the Darien Indians (see "Buccaneer surgeons," *BRITISH MEDICAL JOURNAL*, August 26th, 1922, p. 397). Mr Dingwall tells us in his preface that this volume is to be the first of a series of similar studies connected with the sexual life of man. We hope that the subjects of these future volumes will be better worth the exercise of that knowledge and patience which the author evidently possesses.

ANNALS OF MEDICAL HISTORY

THE centenary of J M Charcot's birth on November 29th, 1825, is celebrated in the September number—the third of the seventh volume—of *The Annals of Medical History*³ by an editorial and reproductions on the cover and frontispiece of portraits of the famous physician of the Salpêtrière. Of the eight articles two deal with the black death—first by Dr H B Allen, on its social and economic results, paying a just tribute to Dr Raymond Crawford's monograph on *Plague and Pestilence in Literature and Art*, Dr Stephen D'Isray presents the official medical opinion of the Universities of Paris and Montpellier on the black death in the fourteenth century. Dr W G Aitchison Robertson gives an interesting sketch of the versatile Sir Kenelm Digby's *Choice and Experimental Receipts in Physic and Chirurgery*, the receipts deal with all manner of diseases, and are mostly examples of polypharmacy. Malpighi's descriptive essay *De Renibus* (1666) is for the first time translated into English by Dr J M Hayman, jun., of Philadelphia, who provides an introduction and illustrations from Vesalius and Bellini for comparison with those of Malpighi. In an article entitled "The ether tragedies," Dr J Moores Ball describes how Dr Charles J Jackson in 1842, having inhaled chlorine, got relief from inhaling ether, and thus accidentally discovered ether anaesthesia, he communicated it to W T G Morton, who, like Horace Wells, tried to claim priority for it, Morton patented it as "letheon", he died of acute mania, and Wells, after anaesthetizing himself with ether, committed suicide. But Dr Crawford Williamson Long had, in 1842, removed a small cystic tumour of the jaw under ether, though he did not lay claim to priority until 1854, when Dr Jackson at once admitted it. This is followed by a fully documented account of Dr Long by Dr Francis Long Taylor of Athens, Georgia. Sir Humphry Rolleston outlines the life and activities of Caleb Hillier Parry of Bath, where a memorial plaque on his house was unveiled during the recent meeting of the British Medical Association. The career of Thomas Dent Mutter, one of the leading surgeons of Jefferson College, Philadelphia, is dutifully described by Dr J H Gibson.

NOTES ON BOOKS

WE welcome a new edition of Sir HUMPHRY ROLLESTON'S essay, *On Writing Theses for M B and M D Degrees*,⁴ for it is one of the best, as it is one of the shortest, of medico literary first aid manuals. It originally appeared in the *St George's Hospital Gazette* in 1911, and when republished in pamphlet form was made the subject of a leading article in our issue of March 9th, 1912 (p. 565). In a prefatory note the author says that "it has now been reprinted with a few alterations and additions." This is an understatement: the changes are perhaps not many, but they are clearly the result of very close and careful revision. As we said of the first edition, this little work should prove of great value to those who have to write theses, and we might add that many others would derive profit from reading it. Its twenty-eight short pages form an excellent and practical supplement to the *Notes on the Composition of Scientific Papers*, by Sir Humphry Rolleston's great predecessor in the Regius Chair of Physic,

¹ *L'Inconscient*. Par le Dr A Hesnard, Professeur à l'École de Santé Navale. Encyclopédie Scientifique publiée sous la direction du Dr Toulouse. Paris: Octave Doin, 1923. (Cr. 8vo pp. viii + 287, 9 figures, 12 fr. post fr. 13.20 fr.)
² *Male Infibulation*. By Eric John Dingwall. M.A. London: John Bale Sons and Daniel Ltd, 1925. (Cr. 8vo pp. vi + 145, 7 figures, 1 plate, 10.6d net.)
³ *Annals of Medical History*. Vol. vii, No. 3. By Francis R. Packard, M.D. New York: Paul E. Baillière, Tindall and Cox, 1925. (8½ x 12½. Sub.cription in Great Britain £2.2s. per volume of four numbers.)
⁴ *On Writing Theses for M B and M D Degrees*. By Sir Humphry Rolleston, Bt, K.C.B., F.R.C.P. Regius Professor of Physic in the University of Cambridge. Second edition, revised. London: John Bale Sons and Daniel Ltd, 1925. (6 x 4½ pp. 28, 1 net.)

with which, as he justly says, every candidate for a Cambridge degree should be familiar. For the benefit of those who have not yet made its acquaintance, we may say that Sir Humphry Rolleston's pamphlet begins with a brief historical and bibliographical introduction, this is followed by notes on how to find a subject for a thesis, and on how to frame a satisfactory title which explains clearly but in the fewest possible words its scope, a brief definition of what a thesis should be, hints on how to work up a subject and arrange the material, guidance on the collection, arrangement, and verification of references, and a concluding note on the composition and revision of the essay. It is almost unnecessary to add that in all respects the author follows his own advice.

Dr WEBB and RIDER, both of them medical officers of tuberculosis sanatoriums in Colorado, have issued a second edition of their little book, *Recovery Record*.¹¹ It contains instructions for the sufferers from pulmonary tuberculosis, and deals with such matters as personal hygiene, the methods of rest to be employed, the best means of employing the mind during physical rest, amusements that may be engaged in, warnings as to accidents and obstacles that may be met during the rest treatment, it owes its title to a series of charts on which is to be entered a diurnal record of temperature, pulse, weight, and any particular point to which the attention of the physician is directed. The patient is expected to make and record these observations for himself. On the charts are printed pithy sayings from many authors directed towards maintaining the moral of the patient. The authors state that in their experience "if such a record is to be kept the patients are usually the ones who must keep it, and because nearly all of them can be trusted to do so." The effect of the daily observations and the comparisons of these records by the patient upon his mentality has to be taken into consideration, but most tuberculous patients are of such a hopeful disposition that there may be little risk of their being injuriously affected by too much knowledge of their own condition.

Dr JEAN BROADHURST'S book *Bacteria in Relation to Man*¹² is a laboratory manual for students of bacteriology, and especially for science students. Medical students would not find sufficient information about pathogenic bacteria, nor would they perhaps have the patience to plod on through the earlier chapters on yeasts and moulds. In fact, we think but few students in this country are likely to find this book helpful to them. Not that in substance it is otherwise than wholesome—we find it crammed full of most reliable information and excellently illustrated. The only fault we find with the book is in its design. A great deal of it is in the form of notes, arranged presumably to supplement a course of lectures given by Dr Broadhurst. It might be possible for some singularly industrious student to fill up the gaps from other books recommended in the text, but such a student is a rarity and could be better employed otherwise. We have no doubt, however, that the book will be useful to teachers of bacteriology because of the well planned exercises it proposes, and it will be useful also as a work of reference, especially in those sections dealing with non pathogenic germs.

The fifth edition of *Infections of the Hand*,¹³ by Dr ALLEN B. KANAVEL has been issued. In the review of the fourth edition (November 18th, 1922, p. 982) we indicated the importance of the work from the point of view of industrial diseases, in the new edition greater emphasis is laid upon the preservation of function. The various procedures suggested in this respect and the pictures showing methods of splinting increase the value of the book considerably. The illustrations generally are a valuable feature, but the many records of cases introduced render the book rather difficult to read as a whole, though valuable for reference. The other good features of the volume to which we referred in our previous review are all retained.

We read in the Introduction to a small book on *Ophthalmic Nursing*¹⁴ by the matron of the Western Ophthalmic Hospital, London, that "nurses without much ophthalmic experience are often heard to remark that of all surgeons, ophthalmic surgeons are the most exacting and needlessly fidgety about

their cases." If they are not exacting they ought to be, for there is no branch of surgery so delicately specialized, nor one in which good results are so likely to be sacrificed through inexperienced nursing. The book, which embodies the author's experience in the Western Ophthalmic Hospital, London, treats in considerable detail, and with the lucidity the public addressed requires, of all aspects of ophthalmic nursing, the routine of medical treatment in the wards, and of surgical technique in the theatre. Its careful perusal should go a very long way to enable a nurse to meet the requirements of the most exacting surgeon.

The primary object of Dr LOUIS L. BISCH'S book entitled *Clinical Psychology*,¹⁵ is to give teachers a working method by which to recognize an atypical child in the classroom and to know how best to handle the situation. It is, of course, most desirable that the school teacher should have some knowledge of mental deficiency, but much of the detailed information given in this book would seem to exceed the knowledge required by the readers for whom it is intended. Thus the volume commences with a comprehensive schema, covering twenty pages, for taking case histories and carrying out physical and mental examinations. To put this schema into practice requires, as the author states, six separate workers—the teacher, a secretary, a psychologist, a social worker, a general physician, and a mental expert to estimate the value of their observations. The rest of the book, which deals in an elementary way with the various types of abnormality in children and provides an excellent account of mental testing, will be found useful by teachers and all who come in contact with the problem of the defective. The detailed methods of examination described by the author will be of value to a psychiatrist entrusted with the organization of a mental clinic. They will give him some idea of the assistance required if the clinic is to be developed along ideal lines, for no such clinic can be complete nor its work effectively carried out by the psychiatrist unless he has the collaboration of the social worker, the school teacher, and assistants trained in routine methods of psychological examination.

¹¹ *Clinical Psychology*. By Louis E. Bisch, M.D., Ph.D. Baltimore: Williams and Wilkins Co. London: Baillière Tindall and Cox. 1925. (Med. 8vo pp. xiv + 346. 17 plates. 15s. net.)

PREPARATIONS AND APPLIANCES

Caprokol (Hexyl Resorcinate)

We have received from the British Drug Houses, Ltd., samples of their new preparation caprokol. Hexyl resorcinate was introduced to Leonard of Johns Hopkins. He claimed that it was a more powerful substance hitherto employed for this purpose. During the past year the drug has been used extensively in therapeutics with very favourable results. The drug is characterized by powerful antiseptic action and low toxicity. In particular it seems to have been proved that prolonged administration of full doses produces no ill effects on the urinary tract. Its special value lies in the fact that it has a powerful bactericidal action in alkaline urine as well as in acid urine. For adults the dose of caprokol (hexyl resorcinate B.D.H.) is 0.3 to 0.6 gram three times a day. The production of this substance appears to represent an important advance in urinary therapeutics. The drug is issued in capsules containing 0.15 gram caprokol in a 25 per cent solution in olive oil. The price of twenty five capsules is 7s. of fifty 13s., and of a hundred 25s. It can also be obtained in bottles containing 4 fluid oz. of a 2 per cent solution in olive oil. Each teaspoonful of this contains about 0.1 gram caprokol. The price of a bottle is 5s.

Opioidine

We have received from Messrs Macfarlan and Co. specimens of their preparation opioidine and also other specimens intended for use in the production of "twilight sleep" in which it is combined with scopolamine. During recent years evidence has accumulated that the administration of the mixed alkaloids of opium has advantages over the administration of pure morphine and opioidine is a preparation containing the mixed alkaloids. One part of it is equivalent to five parts of opium and therefore consists of about equal quantities of morphine and other opium alkaloids. Opioidine is issued by the manufacturers (109 Abbey Hill, Edinburgh and 32, Bethnal Green Road, London E1) in tablets for oral administration (twenty five for 1s. 3d. or a hundred for 3s. 6d.) and for hypodermic administration (twenty five for 2s. or a hundred for 5s. 6d.). Sterile opioidine solution is issued also in ampoules each representing half a grain of opioidine (1s. 9d. for six ampoules and 2s. 9d. for twelve). The drug can be obtained in powder—in tubes (1 gram is 3d. or 10 grams 9s.). The mixture of opioidine and scopolamine is contained in ampoules each containing 1/3 grain opioidine and 1/150 grain scopolamine (2s. for six or twelve for 3s.). The advantage claimed for the preparation is that by using the mixture of opium alkaloids the full therapeutic effects of morphine can be obtained with the use of smaller quantities than when this alkaloid is given alone and hence that there is less danger of producing toxic effects.

THE TREATMENT OF INSOMNIA

On modern therapeutics it is justly demanded that the treatment of symptoms shall be based upon physiological principles. The nature of sleep, however, is obscure. The phenomenon is of a mental order, a natural state of unconsciousness, and of the physiological processes underlying this we know as little as of those belonging to consciousness. The latter state may be assumed upon far evidence to depend upon the activity of nerve cells in the brain, probably the cells of the cerebral cortex, and the natural inference is that unconsciousness and sleep are the result of cessation of function in these cells.

Starting from this assumption many theories have been put forward from time to time to explain the periodic recurrence of sleep as a part of the twenty-four hour cycle. Of these the theory of cerebral anæmia has been widely accepted, and has so far gained credence that plans for the treatment of insomnia are sometimes based upon it. Actually, though the theory is at first sight attractive in its simplicity, the evidence in support is uncertain. Dating from the original observations of Arthur Durham upon dogs whose brains were open to view through trephine holes, it has been maintained that the volume of the brain is diminished during sleep, and its surface paler. Experimental observations with the plethysmograph upon human beings have shown that in sleep there is, as judged by this method, a dilatation of the vessels of the limbs. It has also frequently been observed that during ordinary nocturnal sleep the blood pressure is subnormal. Upon such evidence it has been assumed that sleep is due to a diminution of blood supply to the cortical cells below the level necessary to maintain their activity, and that this state of relative anæmia is brought about through fatigue of the vasomotor centre allowing the systemic arteries to dilate and so deplete the cerebral circulation.

Reference to subsequent observations shows that the foundations of this theory are insecure. Durham's experiments have often been repeated, but with discordant results. The great Italian physiologist Mosso, whose work at one time strongly supported the theory of cerebral anæmia, was forced eventually to admit that the appearances of the brain during sleep were so variable that no definite conclusions could be drawn from them. Shepard, an American physiologist, published observations upon a man with a trephine hole, which led him to the conclusion that the volume of the brain as well as of the limbs is increased during sleep. Other observers have shown that the fall of blood pressure, which normally occurs in nocturnal sleep, is not a necessary accompaniment of the sleeping state, but an expression of the nocturnal ebb of bodily activities which occurs in one accustomed to sleep at night. This ebb can be neither the direct cause nor the result of sleep, for it is still demonstrable at night time when the subject is kept awake. Thus,

other conditions being equal, a man's blood pressure will be higher when he is asleep during the daytime than when he is awake at night.

In the light of such observations Piéron, in his comprehensive monograph of 1913, concluded that the hypothesis that sleep was due to cerebral anæmia was no longer tenable. He himself made some observations upon animals which led him to believe that the prime cause of sleep is the accumulation of toxic bodies in the blood, but postulated that these must act upon some nervous centre with a specific sensibility. It is indeed difficult to explain the phenomena of sleep, especially the acts of going to sleep and waking, without assuming some reflex mechanism to be the final step. Dr C. P. Symonds, in an address to the Oxford Medical Society, recently published in this JOURNAL,¹ put forward his case for the belief that such a reflex centre exists in the mid-brain, and acts—possibly in response to accumulated toxins—by cutting off from the cortical cells the flow of afferent stimuli upon which their normal activity depends. The existence of such a centre is hypothetical, but is supported by clinical observations upon cases of tumour of the third ventricle in which pathological diosmness has long been recognized as a prominent symptom. Further evidence may be found in encephalitis lethargica, in which there is a noteworthy association of sleep disturbance with lesions of the upper mid-brain.

The discussion in the Section of Neurology and Psychological Medicine at the Annual Meeting of the British Medical Association this year, with the full report of which this issue opens, contains abundant evidence of the interest shown by practitioners in the treatment of insomnia, and of the wealth of practical experience available. As a symptom sleeplessness may be the main issue of the illness or an incident only in the campaign, but is a symptom it demands immediate and effective treatment. The reader of the discussion cannot fail to be impressed by the variety of methods which in different hands have proved efficacious. Such an observation suggests that an important factor in the treatment is the belief of the physician in its efficacy and the communication of this belief to the patient. This point is well illustrated by Dr. Harry Campbell's story of a lady who invariably obtained sleep with the aid of a placebo pill. Sleeplessness, however, is not always so amenable to suggestion, and the question must often arise whether, if other methods fail, we should allow the insomnia to continue or should have recourse to drugs.

When sleeplessness is due to physical discomfort or pain, as Dr. Robert Hutchison pointed out in his opening remarks, there can be no objection to drug treatment, seeing that we are usually dealing with a disease of short duration in which the promotion of sleep, if necessary by artificial means, is essential for the maintenance of the patient's strength. In those cases, however, in which the insomnia is of psychogenic origin, or has persisted as a habit after some physical disease the use of hypnotics is more questionable. There are two main objections: first, the possible toxic effect of hypnotic drugs given over a long period; secondly, the danger of promoting a habit. As regards the first objection, there can be no doubt that every hypnotic, if effective, must have some toxic action. As Claude Bernard once said, there is only one difference between a drug and a poison—a difference of dosage. The patient who has

taken a sleeping draught is usually aware of a certain heaviness and sense of intoxication next morning. The chief danger, however, is that the drug, if given continuously, may damage the organs of excretion and so lead to cumulative poisoning. Upon this point Dr Mackenzie Wallis quoted some observations which he has made upon the hepatic and renal efficiency of patients who had been taking medicinal continuously for several months. In no case could he find evidence that the functions of liver or kidney had been impaired. As to the form of establishing a habit, Dr Hutchison suggests that this is a bugbear, and that the possibility of the insomnia becoming a habit is a much more real danger. The drug habit peril is doubtless fostered in the public mind by newspaper reports of suicide in persons who are stated to have been suffering from insomnia. But, as Dr Henry Devine suggested in his contribution to the debate, the insomnia of such persons has probably been but one symptom of a mild psychosis of the melancholic type, and the suicide another. His plea for the early recognition and proper care of such cases deserves wide appreciation.

Against the possible disadvantages of hypnotics in the group of cases under consideration must be balanced the harmful effects of the insomnia itself. Upon this question some recent investigations in America have thrown an interesting light. In human beings who have been kept awake continuously for periods as long as 115 hours, Kleitman and his fellow workers have been unable to observe any effects upon the bodily or nervous systems. Even such tests as involve naming of opposites, cancellation, colour naming, mental arithmetic, and reaction time, were performed as correctly at the end of the experiment as at the beginning. The sole result of the prolonged sleeplessness appears to have been an increasing sense of extreme weariness and discomfort. Yet it is well known that insomnia, if extended not far beyond these limits, may lead to death. Such observations serve again to remind us that the physiologists are still far from the solution of these problems. To supplement a course of side the ill effects of insomnia, it is suggested by Sir M. J. B. Broadhurst. On the clinical side the singularly industrious and undoubted other books of sleeplessness are undoubtedly a rare treat. Crig, speaking with the weight of long experience, considers insomnia as an important cause of mental disorder, and for this reason strongly advocates the early use of hypnotics.

The general opinion appears to be that in symptomatic insomnia treatment by hypnotic drugs is justifiable. It is not, however, to be regarded as a desirable end, and should be anticipated if possible, or if necessary should be supplemented by other methods. Of these other methods it must be admitted that, in the present state of our knowledge, their basis is empirical, and that in all of them the element of suggestion is an important part.

RHEUMATIC INFECTION IN CHILDHOOD

When the Sections of Diseases of Children and of Public Medicine met jointly, at the Annual Meeting of the British Medical Association in Bath, to consider the early diagnosis and preventive treatment of rheumatic infection in childhood, a distinct advance was made in the attitude adopted towards the consideration of this serious crippling malady of early life.

Since Dr F. J. Poynton publicly addressed himself to the question of the prevention of heart disease, in a lecture which we published in the *BRITISH MEDICAL*

¹ Mary A. M. Lee and Nathaniel Kleitman. Studies on the Physiology of Sleep. *Am. Jour. of Hygiene* 67: 141, 1922, 24.

JOURNAL on June 2nd, 1923, the subject has received attention from various quarters. In the same year, at the Portsmouth Annual Meeting, it was discussed in the Section of Medicine. As a result of that debate the Council of the Association appointed a subcommittee to study the rheumatic problem, and it is hoped that the reports of that committee will be available to the medical profession within the next few months. The Medical Research Council also has been promoting investigations into acute rheumatism along several lines, notably with regard to the environmental and the bacteriological factors. The collaboration of the Sections of Public Medicine and Diseases of Children at the last Annual Meeting for joint discussion of rheumatic infection in childhood marks a further step in the right direction. It is interesting to note that during the same week the subject was discussed at the Child Welfare Section of the annual congress of the Royal Sanitary Institute. May we hope that the recent announcement by Lord Knutsford of an anonymous gift of £50,000 to the London Hospital for research with special reference to rheumatic disease is an earnest of the interest the public will take in the attempt to lessen the ravages of rheumatism in the community when their attention is properly directed thereto?

The discussion last July at Bath centred round early diagnosis and preventive treatment. These two aspects of the subject are closely connected, as it is well recognized that only in the early stages of the infection is it possible to ward off the more serious manifestations of acute rheumatism, though it must at the same time be recognized that in some patients the first effect of the disease is indicated by hopeless crippling of the heart.

Early diagnosis implies a knowledge of all the possible first manifestations of the disease, and the early recognition of those cases in which there is no complaint of joint pains and in which the heart is not yet obviously implicated. Preventive treatment, including the introduction of the use of prophylactic penicillin, is the prevention of relapses, and the possession of ability to make an early diagnosis and of a knowledge of etiological factors at present only imperfectly understood.

The contribution by Dr Askins to the discussion was noteworthy in showing what can be done when the medical officer of health is in sympathy with the ideals of the local profession. By collaboration with Dr Carey Coombs and Dr Herapath the rheumatic cardiac problem in Bristol has, for some time past, been pursued on well accredited lines. Dr Poynton's reference to the hospital at Hartfield in Sussex for girls and small boys gives an indication of what benefit may be expected from prolonged residence in the country under suitable conditions. It is striking testimony to the methods adopted at this institution that, out of the 123 cases admitted during the year, only two developed fever and rheumatic pain. Similar results have been reported from the few institutions in the country, such as the Baskeville Hospital School at Birmingham, which make a special point of looking after rheumatic children in the early stages of the disease.

Before prevention of the rheumatic infection can be placed on a sound basis, more definite information is needed as to the environmental causes of the disease. But even without that knowledge active treatment in the earliest stages, and prolonged convalescence in country hospital schools, are calculated to do much to limit the extent of rheumatic heart disease, which is at present a reproach to twentieth century medicine.

THE PANEL CONFERENCE

The annual Conference of Local Medical and Panel Committees was held last week in the Great Hall of the British Medical Association's new House in London. A full report will be found in the SUPPLEMENT (pp 149-157). This was the first of such Conferences to be held at the Association's new headquarters, and the first general meeting of any kind to take place in the Great Hall since the Royal opening ceremony on July 13th. For the first time too, Dr Le Fleming occupied the chair, and Dr Dun presented the report of the Insurance Acts Committee as its chairman. The latter said that he "could not recall a conference agenda so free from controversial matters." Nevertheless, some of the subjects dealt with were of much importance, and the two chairmen are to be congratulated on a useful and successful meeting.

An unexpected item was a motion, brought forward by Dr Fothergill of Brighton as a matter of urgency, and seconded by Dr P. Macdonald of York, declaring confidence in the Insurance Acts Committee as 'the one and only medical body authorized to defend the honour and interests of insurance practitioners and to voice their wishes,' and calling on all Local Medical and Panel Committees to give it their loyal support. During the last year or two another medical body has taken upon itself to call a conference, not merely of its own members but one to which Panel Committees, as such, are asked to send representatives, on the day before that on which the recognized annual Conference of such committees is to be held. Such action must tend to produce disunion and create difficulty, and the position is aggravated when, as has happened this year, in another conference proceeds to appoint its own deputation to make representations to the Ministry of Health on behalf of insurance practitioners and of some Panel Committees. The dangers of the position are quite obvious, and though these may seem hard words there are times when plain speaking however distasteful, is necessary. All the more, therefore, is it a matter for surprise that one member of the Insurance Acts Committee should have allowed himself to be appointed a member of the proposed deputation. In view of such action it is satisfactory that the resolution calling for loyalty to the Insurance Acts Committee alone, through the Conference which it alone is authorized to call, was carried by an overwhelmingly large majority. It may be hoped that all Panel Committees will now realize that anything short of this complete loyalty must be dangerous to the interests for which they stand and to those of the medical profession as a whole.

Two other subjects considered by the Conference deserve notice as matters of general interest: the disciplinary action of the Ministry of Health, and the so-called ophthalmic benefit. There has of late been great dissatisfaction and anxiety with regard to the former. The anxiety has been somewhat allayed by the statement of the Minister that he was in agreement with certain general principles placed before him by the Insurance Acts Committee as those in accordance with which such action should be taken. Cases had occurred in which it seemed at least doubtful whether the Minister's decision had been in accord with these principles, and future cases and decisions will no doubt be very carefully watched, because points absolutely vital to the liberties and traditions of the profession may be involved. Meanwhile proposals have been submitted to the Royal Commission

on National Health Insurance for improving the quasi-judicial machinery and procedure set up by the Insurance Acts and Regulations and for removing altogether from this procedure a large number of cases which can more appropriately be dealt with, as they are in private practice, by individual action on the part of doctor and patient. In these circumstances the Panel Conference wisely decided that it would wait the result of these representations to the Ministry and to the Royal Commission before pronouncing any opinion on alternative proposals.

The Insurance Acts Committee, on behalf of insurance practitioners, has recently made, through the Ministry of Health, arrangements with some approved societies whereby the help which these societies give their members towards obtaining special attention for their eyes is placed on a less unsatisfactory footing. A list of ophthalmic surgeons willing to advise insured persons for a modified fee has been drawn up by the British Medical Association. Insurance practitioners have undertaken to give an appropriate certificate in cases requiring this special attention, and the approved societies have agreed to utilize the services of ophthalmic specialists on the list as far as possible. The Conference approved these arrangements in general and considered some proposals for modification in detail. It should always be remembered, in this connexion, that these arrangements are of an experimental nature, that they are very limited in extent, certain large societies not yet participating in them, that they are recognized only owing to the existing state of the law with regard to 'additional benefits', and that the medical profession still holds strongly to its opinion that this benefit, along with all others which are of the nature of medical advice and treatment, should be removed altogether from the administration and control of approved societies.

THE HANDLING AND TRANSPORT OF FISH

THE Food Investigation Board has done good service in instituting an inquiry into the fishing industry, and in publishing, in a special report on the handling and transport of fish,¹ two illuminating surveys of the conditions in which the industry is carried on. In the one Mr Edgar Griffiths describes the conditions in Great Britain, and in the other Mr Crawford Heron those in France. These two reports, when read together, disclose a startling—we might say a scandalous—state of affairs in this country as compared with France. As Mr Griffiths clearly shows, there is a serious lack of co-operative effort on the part of the British interests concerned to ensure the best treatment of the fish from the time it is caught until it reaches the consumer. When it is landed from the trawlers the fish is left for hours on the quay, liable to be trampled on and without ice, although tons of ice are dumped into the sea when the trawlers unload. During transit by rail ice is carried out in a haphazard manner, with resulting injurious variations in temperature. Cooling of the railway vans is no concern of the railway companies. On the contrary, they add to the difficulties by charging full freight rates for the ice employed by the merchants in sending fish by rapid passenger trains. The cost of ice and its freight amounts in consequence to 25s a ton of fish, or about £5 a barrel. The plentiful use of ice is thus discouraged. The boxes in which the fish are packed for transit are used repeatedly until they can no longer hold together. Definite washing and sterilizing are often

¹ Food Investigation Board Special Report No. 25. *The Handling and Transport of Fish*. By Edgar Griffiths and Crawford Heron. London: H.M. Stationery Office, 1955. (8vo pp vi + 25, 12 figures. Price 9d.)

neglected, and it is no unusual sight to see piles of boxes lying in the sun with swarms of flies infesting the pieces of putrefied fish left in them. Conditions at the central market for distribution to retail dealers are not much better. The fish are exposed for sale in the market or outside in the street, it may be for hours, and during that time no ice is added. Ice, which may have accompanied fish in goods vans, is thrown away on arrival. The effect of all this lack of co-ordinated hygienic handling and transport is that from a bacteriological point of view the temperature curve of the fish during the time on quay, in transit, and in central market is open to every objection. In France the conditions are wholly different. The fish are sorted out, on being unloaded from the trawlers, into baskets that are kept scrupulously clean. They are then taken by the buyers to a special packing house, where they are again sorted out, well washed, and packed for conveyance by rail in special boxes, also kept scrupulously clean, with the greatest care and by a method which prevents the fish being bruised and melted ice coming into contact with them. For transport by rail specially constructed vans are used with the object of keeping the interior at a constantly low temperature throughout the journey. On arrival in Paris there is no delay in transferring the fish to the central market and effecting its sale to the dealers. From beginning to end effort, hygienic and economical, is co-ordinated, although the industry in France is comparatively much smaller than in the United Kingdom. It is surprising that, with the knowledge of what can be and is done in France, no action has yet been taken by the railway companies, producers, and merchants to co-operate in this country and effect a radical change in the present antiquated and harmful methods of handling and transporting fish. It is hoped that Mr Griffiths's and Mr Heion's reports will force them to realize how discreditably the industry is carried on in Great Britain, and that public opinion will insist on the removal of the stigma that we are less sanitary than other nations in the method by which one of our chief sources of food is being supplied to the people. Nor can the medical profession remain silent. It should be the first to demand reform in a matter of so much importance to the public health.

VOLTAIRE AND MEDICINE

At the meeting last week of the Section of the History of Medicine of the Royal Society of Medicine, the President, Dr J. D. Rolleston, read the first part of a paper on Voltaire and medicine. In this he discussed Voltaire's relations to individual doctors and the medical profession as a whole, and gave some account of Voltaire's illnesses. Apart from small-pox, influenza, and pneumonia, he does not appear to have had any acute infectious diseases. He was subject to chronic dyspepsia from an early age, and suffered from catarrhal bronchitis, often associated with deafness and aphonia. He frequently complained of febrile attacks, which may have been malarial in origin. His death at the age of 84 was probably due to uraemia following cystitis secondary to enlargement of the prostate. During his long and eventful life Voltaire was brought into contact with medical men on numerous occasions, both professionally and socially. Moreover, his works, particularly his correspondence, the *Dictionnaire Philosophique*, his tales, and to a less extent his historical works and miscellaneous essays and pamphlets, abound with references to the medical profession. In striking contrast, however, with Moher's works, in none of Voltaire's numerous plays which for the countrymen of Shakespeare are the least readable part of his writings, does a doctor figure as one of the *dramatis personae*, nor are there more than one or two vague references to medical matters in any of them. Among the numerous doctors whom Voltaire con-

sulted the best known were Silva, physician to Louis XIV, Boerhaave, whose name occurs often in Voltaire's works, especially in connexion with chemistry, and Tronchin, whom he described as the greatest physician in Europe, and the only one who understood nature. Voltaire was far from being an ideal patient. Like Herbert Spencer a hundred years later, he was too fond of arguing with his doctors and too little inclined to carry out their instructions. He told one of his medical correspondents that he had read more works on medicine than Don Quixote had on chivalry. Throughout his writings many references are to be found to some of the masters of medicine, such as Hippocrates, Rhazes, Serapion, Harvey, and Sydenham, as well as to celebrated anatomists such as Vesalius, Ruysch, Bartholin, and Viennensis, but the medical work with which he was probably most familiar was that of Astruc on the venereal disease. The passages in which Voltaire indulges his satirical humour at the expense of the medical profession are few in comparison with those in which he expresses his admiration and gratitude, and, apart from the stories, are chiefly to be found in his correspondence, where (Dr Rolleston remarked) they are not to be taken too seriously. On the other hand, Voltaire was scathing in his denunciation of quacks, of whom the most notorious was the Swiss aromantist Schuppach, and vented his ridicule on many superstitious and erroneous doctrines connected with normal and morbid processes. Dr Rolleston's paper was accompanied by an exhibition of Voltaireana, mainly arranged by the well known antiquary Mr A. Forbes Sieveking. These objects included an unpublished portrait by Woolidge, the first English edition of the *Lettres sur les Anglais*, which contains a celebrated letter on inoculation, of which Voltaire was an ardent propagandist throughout his life, and the original manuscript of a long English letter by Voltaire, lent for the occasion by Mr Francis Edwards.

ALCOHOLISM AS AN INTERNATIONAL PROBLEM

THE various respects in which alcoholism may be viewed as an international problem were discussed by Dr R. Heed, director of the International Bureau against Alcoholism established at Lausanne, in the Norman Keir Memorial Lecture before the Society for the Study of Inebriety on October 15th. Dr Heed said that in most of the wine-growing countries at the present day the annual production of wine exceeded the capacity of the home population to consume it, and much the same was true of countries which manufacture spirits. The result was that conflicts had arisen of late years between alcohol-exporting countries and small States, such as those of Scandinavia, which have prohibitive or restrictive measures against alcohol. Iceland, for instance, had been obliged to except the importation of Spanish wines from her prohibition law, because the Spanish Government had the power to starve Iceland by refusing to admit her export of fish, the greater part of which went to the Spanish market. The smuggling of liquors, again, had assumed a disquieting character in Northern Europe, and the only effective action must be international. Another result of excessive alcohol production in some countries was to make new highways for the liquor traffic in parts of the world which had hitherto been free from alcoholism. Africa, before European influence began to be felt, was comparatively sober, but now it was suffering from the alcoholic scourge. The same observation applied to some Moslem countries in which the Christian—or, rather, the Western—example has overborne the precepts of the Koran. Another sphere for international co-operation was the investigation of the physiological action of alcohol, on which, in several respects, there was a diversity of opinion. Findings which had been accepted as authentic had not been verified by subsequent experiments. On the question of alcohol and intellectual

labour the experiments of the late Dr Rivers of Cambridge seemed to contradict some of the results reached by Kriepelm and his disciples. Dr Herod suggested that there should be a kind of international competition in scientific research on alcoholism. With regard to the social effects of alcohol, he held it to be important that each country should know something of what had been achieved or attempted by others. In legislation against alcoholism every country had very much the same problems to solve and here again much could be gained from the international study of various fiscal measures, partial or complete prohibition, schemes of disinterested management, and so forth. It was, he thought, a pity that the authorities in the United States, engaged as they were upon a great social experiment, had not organized a systematic and continuous investigation of the effects of prohibition. With the help of specially trained investigators, and at an expenditure of a few hundred thousand dollars, a useful survey might have been made, to the advantage of the world at large. International legislation against alcohol had been partly realized in Africa, where in the colonies formerly belonging to Germany, and now administered by several of the allied powers under mandate, certain stipulations with regard to alcohol had been made. Finally, Dr Herod touched upon the need for making the facts about alcohol widely known to the public. Some nations, he said, had much to learn from the methods of inculcating temperance in other lands, and he mentioned particularly the example of Sweden, where this branch of education had been developed to such a degree as to make it a model. To appeal to the adult population was a more difficult matter than to instruct youth, but here Dr Herod thought that a good deal of general educational work could be carried on through the press. It seems, therefore, that he shares the faith of so many reformers in the availability of the press for all good propaganda. Even with regard to alcohol alone it would be a difficult task enough, without embarking on positive propaganda, to track down and correct the constant errors, some due to negligence and some to invention, which find currency through the news papers. Difficult as it may be to elucidate the truth of a question scientific or other, it may be still more difficult to publish it when elucidated.

SIR HENRY GRAY

In a paragraph on the resignation of Sir Henry Gray published on October 3rd (p. 621) it was stated that he had "found it necessary to resign his position as surgeon-in-chief of the Royal Victoria Hospital, Montreal, and also as lecturer on clinical surgery in McGill University, to which he was appointed about two years ago." In our last issue (p. 770) we published a short letter from Sir Henry Gray, with copies of letters which had passed between him and the secretary of the Royal Victoria Hospital. On October 22nd (too late to take any steps to insert anything in the last issue of the Journal) a cable gram was received from Dr A. T. Brown of Montreal, asking that it should be stated (1) "that McGill University had no part in inviting Sir Henry Gray to come to Montreal, and that at no time did he occupy any position whatsoever on its staff", and (2) "that the Medical Board of the Royal Victoria Hospital had no part either in Sir Henry Gray's appointment or in his resignation." We are not in a position to comment upon the situation, but we may state as a matter of record that it would appear from letters published in the *Montreal Gazette* of September 29th last that on September 24th Sir Arthur Currie, Principal and Vice-Chancellor of McGill University, addressed to Sir Henry Gray a letter putting into writing views he had expressed at a conference with Sir Henry Gray on the previous day. The letter suggested "that the relations which have existed should

terminate," and that in making the suggestion he (Sir Arthur Currie) was not influenced by any personal feeling, but solely by what he regarded as being the best interests of the medical school of McGill University. Sir Arthur Currie said that three things had influenced him. The first was that when he agreed to Sir Henry Gray's request in 1923 to be allowed to give clinical lectures without being on the staff of McGill and without receiving any pay he did so with hesitation, but was influenced at the time by a desire to ease, if possible, a difficult situation. After two years' trial Sir Arthur Currie had become convinced, he wrote, that the arrangement had not worked well and should be terminated. The second was that the difficulties which arose in medical circles, following upon Sir Henry Gray's appointment as surgeon-in-chief of the Royal Victoria Hospital, had created a distasteful atmosphere from which he wished to remove the university. The third was that many members of Sir Henry Gray's staff at the hospital were members of the university staff, and that there was a division of opinion among them, as also among the students of McGill and its medical graduates in various parts of Canada. Sir Henry Gray replied to this letter on September 28th at considerable length. In the course of this reply he said that the condition proposed to him by the Dean of the Medical Faculty on September 12th, 1923, would have pleased him so far as concerned the teaching part of the work of the Royal Victoria Hospital, in a position of subordination to one of his own staff. He had proposed a solution which was unanimously accepted at a meeting of the Faculty of Medicine in September, 1923. The proposal was that in his capacity as surgeon-in-chief to the Royal Victoria Hospital he should teach McGill students but without academic title. Sir Henry Gray agreed that teaching staff, students, and graduates were divided in opinion about the situation, but added that after his arrival in Montreal he was assured by several medical men, members of both staffs, that they had no unfriendly feeling towards him personally, but resented the way in which his appointment had been made.

OLD SCHOOLS AND NEW SITES

We seem as little likely ever to know whether the Duke of Wellington really said that the battle of Waterloo was won on the playing fields of Eton as we are to conjecture what were the songs the snuvs sang which Sir Thomas Browne fondly imagined to be possible. Nor do we know precisely the import of the saying. As a matter of sober fact, however, it is demonstrable that only a very small percentage of the commissioned officers in Wellington's army had received a public school education. Eton and Westminster no doubt supplied a large proportion of the higher ranks and the staff, which however, the humble officers of the line regiments had small hope of entering. Therefore a century ago the number of persons was small whose health and well-being might be affected by the conditions prevailing in the great public schools. Nowadays a very different state of things is evident. It would be a difficult and delicate task to define what constitutes a public school in the popular acceptance of the term but the list of secondary schools for boys in *Whitaker's Almanac* contains the names of nearly 900 in England alone. In his presidential address to the British Orthopaedic Association at its meeting last week in Manchester, one of which in abstract appears in this issue at page 799, Sir Robert Jones commented rather severely on the hygienic conditions which he thinks still exist at our more ancient public schools. We do not know how many of the 900 schools referred to above are boarding-schools but it is certain that many of them are as much modernizations and expansions of ancient grammar schools as for instance Harrow which is a development of the grammar school founded by John Iton in the sixteenth

century Harrow is notoriously "on the Hill," but there are no doubt many other schools which, like Eton and Westminster, are situated on low or even swampy ground on a river's bank, and occupy in part ancient buildings which may not provide the modern advantages of spaciousness, good lighting, ventilation, and present-day comfort. If we understand him correctly Sir Robert Jones would move Eton from its low and often damp site to the southern slope of some neighbouring hill—say, for example, in Berkshire or Surrey, or some bold spur of the Chilterns, but before he could hope to achieve such a result it would be necessary to show that the health of Etonians in general was inferior to that, for example, of the Carthusians, whose school was removed from the close neighbourhood of Smithfield to an ideal site on a hill in Surrey. Yet it is not recorded that Charterhouse has a better health record than Westminster, which still remains to a considerable extent a boarding-school, in the swampy island of Thorney. Perhaps we are pushing Sir Robert's contention to undue extremes, but it is certain that he is right in urging that in our great public schools hygienic surroundings should be as much attended to as in the primary schools of the London County Council and other educational authorities, and it would certainly be a change altogether for the better if medical buildings could be to a large extent abandoned, in favour of the open air, for purposes of study and of sleep as well as of recreation.

SOCIAL EVENING AT THE ROYAL SOCIETY OF MEDICINE

The first social evening of the session at the Royal Society of Medicine took place on October 27th, when Sir StClair Thomson, the President, after receiving the members and guests, gave a short lecture on the medical allusions in Shakespeare. In the library an interesting exhibition (noticed in more detail below), including specimens of plants, herbs and roots mentioned in the plays, medals and portraits of Shakespeare, and portraits of physicians and surgeons of his time, had been arranged by Mr C J S Thompson. Among the distinguished company present were many representatives of the drama, art, and literature, including Sir Sidney Lee, Sir John Martin Harver, Mr Granville Barker, Sir Israel Gollancz, Mr Guy Dawber (President of the Royal Institute of British Architects), and Sir Frank Dicksee (President of the Royal Academy). In the course of his address Sir StClair Thomson remarked that when Sydenham was asked by Sir Richard Blackmore what books on medicine he should study he gave the unexpected reply, "Read *Don Quixote*." The great Sydenham thereby taught that physicians would be incomplete practitioners of their art if they limited their studies to the science of their calling. From Shakespeare there was very much for the physician to learn, and some of the references to medicine were "modern instances." Indeed even in those Elizabethan days of superstition and wholesale drug-taking Shakespeare recognized the *vis medicatrix naturae*, and gave quite a modern idea of curing the patient. He had some common-sense regulations for dealing with digestive trouble: "Unquiet meals make ill digestion." For the treatment of fainting attacks he set out the very first principle upon which the public was still slow to act: "Stand from him, give him air." Three centuries before the profession had thought of open-air treatment here was Shakespeare advising, in *Love's Labour's Lost*, "the most wholesome physick of the health-giving air," and in *King John*, "being brought into the open air would allay the burning quality of that fell poison which a salety him." The advantages of travel and change of scene particularly in cases of neurasthenia, were brought out by the King of Denmark when speaking of the projected trip to England of his young stepson: "And that seas and countries different" might "exel"

this something-settled matter in his heart." Mirth and merriment appeared as part of the doctor's prescription in *The Taming of the Shrew*, and "sweet recreation" in *The Comedy of Errors*. With regard to alcohol, Shakespeare painted in vivid colours the loathsomeness and degradation of alcoholic excess, but, on the other hand, he praised wine taken with discretion. He also made it plain that over-eating and starvation were equally unhealthy. Nerissa, in *The Merchant of Venice*, exclaimed, "For aught I see they are as sick that surfeit with too much as they that starve with nothing." He insisted also on the importance of sound, sufficient, and regular sleep—"sleep that knits up the ravell'd sleaze of care." The practice of suggestion he appreciated, and from *Is You Will It* seemed to think that this remarkable power might be used to resist even the onset of death. Shakespeare regarded sympathy and the art of inspiring encouragement as essential to the doctor.

Our remedies oft in ourselves do lie
Which we ascribe to heaven

In the difficult task of pronouncing a gloomy prognosis some help was to be gleaned from these wise pages. Shakespeare even suggested that the physician might be spared the actual telling of bad news and the patient the shock of hearing it.

'He that but fears the thing he would not know
Hath by instinct knowledge from others eyes
That what he fears is eluded'

The justification for *crasmodis* was to be found in the wise note-taking of the Scottish doctor who attended Lady Maebeth. The fears of sick folk were illustrated by Lady Constance in *King John*, and Lear excused the behaviour of his son-in-law by attributing it to a physical condition, and even sought a pathological explanation of his daughter's ingratitude. Sir StClair Thomson concluded by saying that Shakespeare must remain one of the greatest masters of medicine for his astonishing acuteness of observation, his familiarity with the ways and thoughts of frail humanity, his discrimination of human disorders according to age, sex, and circumstance, his sweet reasonableness and deep human sympathy, and his profound knowledge of those conditions of physiology and pathology which might be studied in the dark life of the street, the market, the tavern, the court, and the camp, which were not subject to errors in investigation and were eternally true. Shakespeare's plays would be read by physicians when most of the books in the library of the Royal Society of Medicine were lying on the dust-heaps of literature. Mr Granville Barker, in proposing a vote of thanks, remarked that Sir StClair Thomson had omitted to say that Shakespeare married his daughter to a practising physician, Dr John Hall, who had a very good practice at Stratford-on-Avon. It was also to be remembered that Shakespeare made a quack doctor the heroine of one of his plays, though he would not suggest that she represented his ultimate opinion of the medical profession. Sir Ernest Pollock, Master of the Rolls, seconded the vote of thanks and had something to say about Shakespeare's connexion with the law and (if rumour spoke truth) his disappointments as a litigant.

SHAKESPERIANA MEDICA

To illustrate the address which was given by Sir StClair Thomson at the social evening of the Royal Society of Medicine last Tuesday, the curator of the Wellcome Historical Medical Museum, Mr C J S Thompson, brought together a remarkable collection of objects associated with the history of the dramatist or referred to in his works. These consisted of portraits of English physicians and surgeons who were contemporaries of Shakespeare, specimens of herbs, roots and other drugs mentioned in the works, pictures representing imaginary characters and old books dealing with the subjects referred to in the

lecture The oil painting of Dr Caius represents a grave and thoughtful personage such as that well known physician and benefactor to the University of Cambridge is likely to have been The fiery and somewhat ridiculous Frenchman of *The Merry Wives of Windsor* only in name resembled the English physician, whose services to scholarship and learning deserved a better record in the book of fame There is no trace visible in this portrait of the effects of the long and fierce controversies which embittered the latter days of the second founder of Gonville and Caius College The portraits of Butts and Chambray call for little notice There also were the engravings of William Harvey, of William Gilbert, the author of *De Magnete*, of whom Dryden prophesied "Gilbert shall live till lordstones cease to draw", of the great clinicians and surgeons Sydenham, Glisson, Woodall, Clowes, and Bannister Specimens of thirty-six drugs were displayed These included ratbane or white arsenic, also bebenon, which has with great plausibility been identified with yew, of which both the berries and the leaves contain a very deadly poison, and according to Taylor yew-ter has been a vulgar and dangerous abortifacient, but it is doubtful if a liquid extract dropped into the auditory meatus could have killed the King of Denmark, as suggested by his ghost The Wellcome Museum is peculiarly rich in specimens and drawings and paintings illustrative of the mandrake, going back as far as 4,000 years B.C., which date is assigned to a record on a Babylonian clay tablet of the mandrake The habit of this plant of growing with a double root—very often with rootlets which a little imagination may easily interpret as sexual appendages—has no doubt had much to do with its sinister reputation, especially when its poisonous nature is remembered But as a drowsy syrup it must have been very much inferior to preparations of opium The picture of *The Apothecary*, by Strey Marks, R.A., does duty well for the vendor of poison to Romeo, although he appears to be a man of too good intellectual development to be fitly represented on the boards, even of Mr Crummles's theatre, by Smike Another picture, *The Water Caster*, by Holman, illustrates Falstaff's reference to diagnosis by inspection of urine A most extensive collection of engravings purporting to represent Shakespeare, some of which have been made to enforce arguments in the discussions as to the authentic likeness of the poet, was lent by Mr M. H. Spielman and exhibited on screens Mr Spielman also lent his collection of medals of Shakespeare, among which are to be seen a bronze and a silver one which were awarded in the years 1851 and 1852 respectively to the former editor of this Journal, Mr Ernest Hart, when he was a pupil at the City of London School Touching for the king's evil is mentioned in *Macbeth*, hence there were exhibited a number of gold angels and other "touch-pieces," which were given to the subjects of the royal treatment and hung round the neck It will be remembered that the great Samuel Johnson was "touched" for scrofula by Queen Anne Among the books were the English translation of the Latin work by Dr Hall of Stratford, who married Shakespeare's daughter This was entitled in the translation by Dr James Cook, or Cooke, *Observations on English Bodies* Cook was himself the author of *The Marrow of Churgery* The title-page bears the following announcement "In the Close is added, Directions for Drinking of the Bath-Water and Ais Cosmetica or Beautifying Ait by H. Stubbs, Physician at Warwick, 1683" This is one of the very earliest English treatises on the use of mineral water There were also shown herbals and P. Jeriard's *Flowers Mentioned in Shakespeare's Plays and Poems*, and a book, lent by Sir D'Arcy Power, in the cover of which is inlaid a piece of the ciabtree at Badford-on-Avon under which the poet is

scandalously reported to have slept off a drinking bout Facsimiles of the will and of the conveyance and mortgage of Shakespeare's house in Blackfriars complete this most interesting exhibition

THE TRANSMISSION OF FOOT AND MOUTH DISEASE

Foot-and-mouth disease is still present in this country, and although at the moment only local outbreaks have been recorded, it shows signs of spreading It has recently broken out again in America also Emphasis must once more be given to the fact that our knowledge of the disease is still in a very uncertain condition, especially with regard to the methods of transmission The recent report of the Foot-and-Mouth Disease Committee indicates that although small mammals, such as mice, rats, and fieldmice, may be experimentally infected, natural cases of contagion do not occur, and that birds can apparently be excluded as carriers of the virus The larger mammals, such as dogs and their allies, are not yet, however, free from suspicion, and we understand that the police in certain areas have instructions to treat all dogs not on leads as strays, and to arrest them, and, if they think proper, destroy them While it is true that the Americans claim that at least one of their outbreaks was due to a wandering dog, it seems a rather futile proceeding to arrest dogs when so many obvious carriers, such as man, are allowed to come and go as they please It is now almost a commonplace to find that in a chain of farms owned by a single person, the disease breaks out first in one, then in another, while the intervening farms go free The evidence that man is the principal mechanical carrier—on epidemiological evidence alone—is striking, and steps should be taken to explore the possibilities in this direction When this has been done the minor transmitters may be tackled, it seems, however, useless to eliminate these while the major are allowed to continue to spread the infection unchecked In the meantime, while this is being done, we would suggest that the Committee should tackle the dog as a carrier, not only in the laboratory, but in the field

STANDARDIZATION OF THERAPEUTIC SUBSTANCES

The Pharmaceutical Society of Great Britain has appointed Dr J. H. Burn director of the new laboratories to be established by the society to provide facilities for biological tests such as are imposed under the Therapeutic Substances Act, which became law on August 7th, 1925 The Act comes into force on a date to be fixed by Order in Council This date must not be earlier than one year nor later than two years after the passing of the Act The laboratory will be used also for carrying out researches in pharmacology, including the methods of biological assay Dr Burn graduated in medicine at Cambridge in 1920, he is a member of the staff of the Medical Research Council, and holds the post of pharmacologist in the National Institute for Medical Research at Hampstead He was Michael Foster student in the University of Cambridge and assistant demonstrator in physiology at Guy's Hospital Medical School He is joint secretary of the Section of Therapeutics of the Royal Society of Medicine, and has been secretary of the Physiological Section of the British Association

The Bradshaw Lecture before the Royal College of Surgeons will be delivered by Mr James Sherren, C.B.D., F.R.C.S., on Wednesday, November 11th, at 5 p.m. His subject is gastro-jejunostomy The Thomas Vicary Lecture will be given by Professor William Wright, D.Sc., F.R.C.S., on Wednesday, November 18th, at the same hour His subject is the mediaeval conception of the anatomy and physiology of the central nervous system Fellows and Members of the College are invited to attend, and others will be admitted on presenting their private visiting cards

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

THE second meeting of the Court of Governors of the London School of Hygiene and Tropical Medicine was held on October 22nd at the University Club, 21, Gower Street. The Chairman, Sir HOLBURN WARRING, presided, and the other members of the Court present were Sir Frederick Andrewes, Colonel H. P. W. BULLOW, Dr R. A. BOLIM, Sir Walter Fletcher, Dr F. E. FLEMANTLE, M.P., Sir HARRY GOSCHEN, Sir WILLIAM HODGSON, Sir W. LESLIE MACKENZIE, Dr J. C. McVAIL, Air-Marshal David MUNRO, Sir George NEWMAN, Sir ARTHUR ROBINSON, Sir WILLIAM SIMPSON, and Sir WILLIAM SMITH, with Dr Andrew Balfour (Director) and Mr R. W. HARRIS (Secretary).

The Board of Management in its annual report, presented to the meeting, records that on August 1st, 1924, the London School of Tropical Medicine became merged in the London School of Hygiene and Tropical Medicine, under Clause 3 of the Charter. The Board and its several committees have held forty-four meetings in all up to the present time. A year ago it decided, on the recommendation of the Building Committee, to hold a limited competition among certain architects chosen for their experience in laboratory construction. Sir FRANK BARNES, Director of Government Works and Buildings, acted as assessor, and on his advice Mr P. MORLEY HORDER, R.I.B.A., was appointed architect on June 25th. Since that date Mr Horder has been engaged, in consultation with the Building Committee, in modifying his design in detail to meet the wishes of the Board. Meanwhile it has been decided to invite tenders for the foundations, which can be proceeded with while the working out by the architect of the final structure is in progress. Although the Board expresses the hope that speedy progress may now be made, it is advised that for a work of this magnitude at the normal rate of construction the building can hardly be expected to be ready for occupation until some time in 1928.

Whether the architect's design can be carried out in its entirety within the limit of the funds available cannot be known until tenders for the whole of the work have been received. The financial position has, however, been improved by the generous action of the Trustees of the Rockefeller Foundation, referred to in our issue of June 27th (p. 1187). Their original undertaking of February, 1922, to provide a sum of two million dollars has been amended by a promise to pay £460,830, being the value of the gift in sterling as at the time of the original undertaking. In this way the Rockefeller Foundation Trustees have cancelled the loss due to the gradual rise in sterling which threatened the school with a decline in the value of the gift of more than £50,000, if conversion had been made at the rate of exchange then established. Of the total sum available £52,610 was spent in 1923 on the purchase of the site for the new building, near the British Museum; this site has frontages on Keppel Street, Gower Street, and Milet Street.

The Board of Management states that concurrently with the task of preparing for the permanent home of the new school, the Education Committee and the Director have given much thought to the general educational organization. In this they have had the advantage of a provisional scheme of studies drafted by a committee set up by the Minister of Health prior to the constitution of the school. The scheme will be finally amended in consultation with the prospective heads of the several divisions of work. The University Grants Committee in compliance with representations made by the Board has made provision for a grant of £5,000 for the academic year ending July 31st, 1926, in part of the sum the Government undertook to provide for the maintenance of the new school. This will be supplemental to the grant of £2,200 made in the past to the London School of Tropical Medicine and now continued for the Division of Tropical Medicine and Hygiene. The total grant of £7,200 is in fact available for the work as a whole. It is additional to the £4,000 per annum provided by the Rockefeller Trustees for the general work of administration, and to the income of the Tropical Division from fees, endowments, and other sources. Application will be

made to the Senate of the University of London to set up Boards of Advisors for the appointment of professors who will be in charge of certain divisions of the School.

The report of the Board of Management was accompanied by the Director's report on the work of the Tropical Division for the year ending July 31st, 1925. The Board noted with satisfaction that the work of the Tropical Division in its first year under Dr Andrew Balfour's direction has made good progress, both in teaching and research, while the accounts show an improved financial position. The session 1925-26, it is stated, should witness the laying of the foundations of the new building, which the Board of Management believe will be a worthy embodiment of the high purposes for which the school has been established. "It should also see some progress with the actual realization of that broad programme of public health teaching for which the School has been brought into existence, and of which the courses of study in the Tropical Division—which necessarily learn largely in the present account of the work of the School—form but one though an integral part."

Both reports were approved by the Court. In the course of discussion stress was laid on the importance of applying the research funds of the School, both capital and interest, to the development of further held stations like that lately established in Southern Rhodesia, and it was agreed that representations to the Board of Management should be made accordingly.

France.

[FROM OUR OWN CORRESPONDENT.]

French Congress of Surgery

WITH the coming of October the life of the medical world begins again. The first symptom of this revival is the meeting of the national Congress of Surgery, an annual event which attracts to Paris the great majority of French surgeons. Patients with symptoms of acute appendicitis which might require an urgent operation would therefore have been wise to defer the crisis, for during the week of the congress they would have run a great risk of not being able to obtain the services of their usual surgeon, nor of any surgeon in a neighbouring town. Thus, the thirtieth surgical congress was opened by M. BOREL, Ministre de la Marine, accompanied by the dean of the faculty, and the number of French and foreign delegates and members present was unusually large. Professor BERARD of Lyon, president of the congress, in his inaugural address, recounted the investigations of the Lyon school into the surgery of bones and joints during the last hundred years, and recalled the great names of BONAULT, OLIER, PONSSET, and JABOUILLY. In concluding he paid a glowing tribute to some of those who had died during the year mentioning in particular the names and the work of DEPAGE, SCHWARTZ, POTHELET, and BERGONIÉ. A subject set down for discussion was the remote results of extirpation of cancer of the rectum. Once again indeed therapy had very few warm supporters.

In connexion with the large concourse of surgeons present at the congress it is not without interest to note how greatly the number of surgeons has increased since the war. Every medical man mobilized was called upon at one time or another to do surgical work, and consequently they went through an apprenticeship from which they sought to draw some advantage. It does not seem that as a rule their hopes have been justified. An attraction towards surgery has also been felt by the young men in the schools, and even first-year students appear to think that he is called upon to be a surgical vedette. Many of them seem to think that surgery is the portal which will enable them to escape from the demands of social medicine, that it will be a refuge for them against the *capitalisation* with which the State now menaces them. Also it may be said, perhaps that the large fees surgeons receive exercise a powerful influence in making them believe that they have a real vocation. *Qui vivra verra.*

Military Medical Liaison

In the campaign against the Riffs which is dragging out its slow course in Morocco aviation is playing a leading part

in the evacuation of the wounded. Down to the time when the present war began more than 1,200 wounded had been evacuated by the air route. At the present time the service is being carried on with great success. The aeroplanes used are old-fashioned fighting machines, repaired and slightly transformed for the new service in which they are now being employed—a service in which great rapidity of flight is not necessary. It seems probable that the experience now being gained will establish the aeroplane as part of the equipment of every ambulance service. It is unnecessary to comment on the advantage the aeroplane presents for the prompt transport of seriously wounded men. It renders them independent of the bad roads which alone are available in certain districts.

Académie de Médecine

A commission of the Académie de Médecine on the safety of travellers is now investigating the possible improvement of methods of medical supervision of persons employed on the railways and in particular of the drivers and point-men. It is ascertained that important posts involving great responsibility may be occupied by general paralytics! This fact naturally gave the members of the Académie a great shock.

A rather striking illustration of the present-day poverty of France is that the grant received by the Académie is insufficient to enable it to warm its own house, and that it will without doubt have to appeal to the generosity of its members. Meanwhile, it has sought to warm itself up by discussing the merits of candidates who will shortly come up for election. Among them is a novel writer who has found morbid and fashionable psychology a mine which has yielded very abundant material.

An Epidemic of Devotion

M. de Massary recently told the Société des Hôpitaux a curious story showing how far the influence of the cinema may go in affecting weak minds. During one week several persons went to a hospital in Paris asking that the whole of their blood should be taken in order that a patient seriously ill should be transfused. The authorities of the hospital were astonished by the repetition of an offer so unusual and instituted an inquiry, which revealed that a cinema popular in the quarter had recently been showing a film in which the heroine was in fact saved by transfusion. No complaint is made of the motives of these persons, who had little to give, but the alienists Maigne and de Fuisac have recently presented to the same society a harvest of medico-legal observations showing that the cinema more often inspires such zealous folk to take the blood of somebody else rather than give their own for transfusion.

G. MORON

Scotland.

PROFESSOR HARVEY CUSHING

PROFESSOR HARVEY CUSHING, M.A., M.D., D.Sc., LL.D., Mosley professor of surgery, Harvard University, and surgeon to the Peter Bent Brigham Hospital, Boston, Mass., to whom the Cameron Prize of 1924 was awarded, delivered three lectures in the anatomy classroom of Edinburgh University on October 19th, 20th, and 22nd. Professor Sir L. Shapley-Schreier, F.R.S., presided at the first lecture, in which Professor Cushing dealt with the circulation of the cerebro-spinal fluid, a subject which had engaged his attention and that of his fellow workers in Boston for a number of years. In the course of his address he pointed out the importance of the cerebro-spinal fluid in relation to diseases of the membranes of the brain, and to tumours in certain localities. He summarized his research on this matter, tracing the course of the fluid from the blood, out of the choroid plexus and by way of the ventricles and subarachnoid spaces to its exit from the cranium. He also dealt with the relation of this circulation to hydrocephalus and outlined the treatment which was now possible for certain cases of the latter condition.

At the second lecture, when Principal Sir Alfred Ewing presided, the lecturer dealt with the pituitary gland, outlining by means of lantern slides his own researches

in relation to this structure. He said that a knowledge of the function of this organ practically began in 1907, when Paulsco, a Rumanian investigator, had found that surprising results followed experimental extirpation of the gland, thus Professor Cushing and his pupils had confirmed in the years 1908 and 1909. The lecturer demonstrated the important bearing which the gland possessed on growth and sexual development, and the relation of its secretion to the elimination of large quantities of fluid. Almost all the pathological symptoms arising in connection with the gland, he said, had reference to defects in the posterior lobe. He also described the result of his operations upon this gland by the intracranial route, the mortality of the operation had been only 2 per cent. He believed that in time to come disorders of the gland might be treated by administration of various endocrine substances and operation might become unnecessary.

The third lecture dealt with brain tumours, and Emeritus Professor Sir Harold Stiles occupied the chair. The lecturer dealt principally with the necessity for using every possible means in the diagnosis of such cases, and indicated the progress that had been made in this field of medicine as the result of labours by many workers in different parts of the world. The chairman, in proposing a vote of thanks to the lecturer, paid tribute to the part he had played in this difficult field of medicine, and declared that no surgeon's education could be regarded as complete unless he had paid a visit to the hospital where Professor Cushing worked, and had seen the spirit in which team work was organized and carried out by him.

On October 23rd Professor Cushing visited the James Mackenzie Institute for Clinical Research at St. Andrews, and in an informal address compared research work carried on in hospital and in general practice. The stimulus to research, he said, was the same—the desire to find satisfactory answers to problems of difficulty. The worker who saw all his patients in an institution (as he did in America) had better opportunities for obtaining records of his special cases and more time and facilities for investigation than the general practitioner. He himself was directly descended from three generations of general practitioners, who had practised in the same district, and one of his most cherished possessions was a collection of the case-books of these ancestors. Not only were they records of illness in individuals, but they provided, by their continuity, material for the study of familial tendencies, and demonstrated the extreme value of accurate and continuous records in medicine. To enhance the value of records, he advocated the employment, wherever possible, of instruments of precision, though they must never overbalance the general judgement of a case. In connection with his special study he warned practitioners that, in cases of cerebral tumour, any of the cardinal symptoms (headache, vomiting, choked disc) might be absent, and, indeed, that cerebral tumours of slow growth might attain considerable size with no symptoms whatever. The intracranial cavity was, in his experience, the commonest site of tumour growth in the body. He spoke of the importance of detailed recording of such a symptom as headache (site, time of occurrence, character, etc.) on Mackenzie's lines. If any symptom was carefully studied in this way important leads were sure to emerge. He commented upon our ignorance of the mechanism of production of headache. In conscious patients direct manipulation of the cerebral substance produced no sensation, but acute pain was experienced if the membranes were pulled upon or an artery clipped or ligatured. Clinical research, whether by specialists or by general practitioners, was carried out by similar means and with the same object. The inquiring mind, that would not rest till it got an explanation, was what mattered.

OPENING OF THE ROYAL (DICK) VETERINARY COLLEGE, EDINBURGH

The Secretary for Scotland (Sir John Gilmour, M.P.) opened the completed buildings of the Royal (Dick) Veterinary College at Edinburgh on October 19th. Professor T. Hudson Berrie, chairman of the board of management of the college, who presided, stated that the buildings had been commenced a few years before the outbreak of the war, and the Government had instructed the board to continue

the work of building, so that the college was partially completed and the work transferred to it from the old college in Chdo Street by 1916. Only within the present year had funds become available for completing the laboratory equipment. The cost of the site and buildings had been over £58,000, and the laboratory equipment had required a further £16,000, making a total of about £75,000. Since the end of the war the number of students matriculated annually had fluctuated between 138 and 173, this year it was 144. The number of post-graduate students had steadily grown year by year, and last session 25 had attended, chiefly for the purpose of taking the Diploma in Veterinary State Medicine. A considerable amount of research was being carried out in the college, and as a memorial of the centenary of its foundation a post-graduate fellowship fund had been established. The Advisory Committee of the Animal Diseases Research Association was also allotted accommodation for research investigations in the college, and an honorary research professor for animal pathology had been appointed. Sir John Gilmour said that the good relations which existed between the board of management and the college and the Board of Agriculture were a matter for great satisfaction. Although the sum spent in building and equipping the college might seem large, it was very small when compared with the value of the work which could be done and of the enormous saving to the country which would result from the improvement of veterinary science. Very close and friendly co-operation was very desirable between veterinary science and medical science, which could learn much the one from the other. Medical science could give great help in locating some of the microbes and parasites from which stock suffered, and veterinary science could solve many of the difficulties which at present baffled health administrators—for example, in giving better milk cattle, clean from tuberculosis.

The Lord Provost, Sir William Sleigh, spoke of the close and friendly relation which had always existed between the Veterinary College and Edinburgh Corporation and said that the college had a world-wide reputation. Sir Harold Stiles pointed out the extreme importance the study of animal pathology had for medical men. He hoped to see in future a school of animal pathology in connexion with human pathology and both subjects taught under the same roof. He knew that hearty co-operation always existed between the Veterinary School and the Medical School of Edinburgh University, and he congratulated the Veterinary College on the work it had done during the last century for preventive medicine and humanity at large.

PREVENTION OF INDUSTRIAL SICKNESS

A meeting of the Council of Industrial Health Education was held in Edinburgh on October 18th, to consider the extension of the work to England, Wales, and the North of Ireland. Sir William S. Haldane, W.S., presided, and the secretary reported that for the first part of the year thirty engagements had been made for health talks to workers' organizations and that for the period from October to December 1925 fifty engagements had been made all over Scotland for similar talks. It was further reported that eight medical men had already agreed to associate themselves with the proposed extension. Sir Thomas Oliver, M.D., spoke on the desirability of the Council's programme being taken up south of the border, and referred to the wide field of work which lay among the industrial population there. The Council decided to deal first with the area covered by Cumberland, Northumberland, Durham and York, limiting the lectures to information which would enable workers to lessen and possibly prevent, diseases and ailments associated with their occupations.

CONVALESCENT BENEFIT

Alderston Convalescent Home, near Haddington, was formally opened on October 10th. This mansion house was acquired last spring by the Scottish National Benevolent Association to be used for the purpose of providing convalescent home treatment for members of the Scottish Rural Workers' Approved Society as an additional benefit under the National Health Insurance Act. The purchase and equipment were provided out of the surplus funds of the

society. The home is situated in the centre of well wooded policies extending to about forty acres, with a fine view over the Lammermoor Hills. It contains four public rooms, twenty-one bedrooms, and three bathrooms, is fitted with electric light, central heating, and other modern conveniences, and has a walled garden, two acres in extent, bowling green, and putting green. Recreation is provided in the form of billiards and musical instruments and wireless installation, and some thirty patients can be accommodated at one time. Mr James Falconer, President of the Scottish National Benevolent Association, in declaring the home open, said that there was a great deal for the benefit of the rural workers to be covered by the surplus funds, and that there were many other ways besides this home in which all the money available could be profitably expended.

CLINICAL MEDICINE MEDICAL EDUCATION

At a meeting of the University Court of the University of Edinburgh on October 19th it was intimated that a legacy had been received from the estate of the late Dr J. Murdoch Brown of £150 for the presentation annually of a silver medal to be awarded to the best graduate in clinical medicine in each year. The legacy was gratefully received by the Court. At the same meeting Dr J. Haig Ferguson, senior lecturer in clinical gynaecology, and Mr J. W. Stuthers, senior lecturer in clinical surgery, were appointed members of the faculty of medicine in the university.

England and Wales.

POST GRADUATE WORK IN NEWCASTLE

The general post-graduate course which began at the Royal Victoria Infirmary, Newcastle-on-Tyne, on October 1st is being attended by fifty-one practitioners. To facilitate clinical teaching the class has been divided into two sections. The meetings are held on Thursday afternoons, and instruction is given each day in clinical medicine, clinical surgery, and pathology, including post-mortem demonstrations. Three special lectures have been arranged as part of the general course, the first of which, on the post-operative treatment of tonsils and adenoids, was delivered by Dr J. Dunlop Lickley on October 1st. Dr R. A. Bolam will lecture on November 5th on the present day treatment of syphilis, and Professor David Burns will give the third lecture on December 3rd on insulin. A special course in midwifery and gynaecology is being conducted at the Princess Mary Maternity Hospital by Professor Ranken Lyle and Dr T. F. Fingland Murray.

In addition to these courses, which form part of the routine post-graduate instruction of the University of Durham, an intensive course of a fortnight's duration commenced on October 12th. It was arranged in conjunction with the Ministry of Health and the Northumberland Panel Committee for the benefit of panel practitioners in the rural areas of Northumberland, and was limited to twelve members, who were selected from the applicants by the Northumberland Panel Committee. The Panel Committee after careful consideration, elected to expend in this way part of its share of the special £10,000 fund which was also applied to the provision of locumtenents for the members of the class. A very comprehensive syllabus, comprising some sixty lectures and demonstrations, was arranged, occupying each morning and afternoon. The first hour of each day was devoted to a course of clinical pathology designed to meet the requirements of general practitioners. The remaining hours were occupied by classes in medicine, surgery, midwifery, gynaecology, eye diseases, and diseases of infancy, the individual subjects being selected with the object of enabling the members to understand the significance and practical application of recent advances in knowledge. The instruction was essentially clinical, and the limited size of the class facilitated the examination of a large number of cases by each member.

MANCHESTER BABIES' HOSPITAL

The new Manchester Babies' Hospital in Burnage Lane, Levenshulme, Manchester, was opened on October 19th by Lord Derby in the presence of a large gathering. The

hospital was founded in 1914 with only twelve cots, as this number proved inadequate for the amount of work that had to be dealt with, the present building has been erected, providing accommodation for eighty children. The cost of the extensions, including the nurses' hostel, amounts to £16,000, of which £12,000 has already been raised. The new hospital is built on one floor, there is a central corridor on one side of which are the wards and on the opposite side bathrooms and the milk preparation room. The building faces south, and the windows are arranged to slide to one side so that the whole space can be thrown open for light and air, while cots can be wheeled out on to the adjoining terrace. The hospital receives grants from both the Ministry of Health and the Manchester Corporation and the latter body reserves a number of the cots for use in connexion with its maternity and infant welfare work. The hospital claims, perhaps correctly, to be second to none, both in the character of the work it carries on and in the nature of its equipment. There is a room fitted out with the most modern type of lamp for "artificial sunlight" treatment, and it is interesting to recall that this method of treatment was adopted by the hospital at a very early period, with excellent results.

TUBERCULOSIS IN LONDON

The annual report of the Metropolitan Asylums Board for 1924 was noticed in our issue of September 26th (p. 579). An additional fasciculus, dealing with tuberculosis, has now been issued. For that disease the Board has 2,265 beds. Both adults and children (either sex) are admitted, and the cases are classified into sanatorium, advanced, pulmonary, and non-pulmonary.

The report contains a series of valuable articles by members of the staff. Dr. James Watt, chief medical officer of the tuberculosis service, notes that at Colindale Hospital the average duration of stay of advanced male adult cases has been shortened in three years from 159 to 117 days, there is much pressure on the accommodation in the three sanatoriums—for men, women, and children respectively—20 to 30 per cent of the cases admitted are not likely to benefit materially, and would be sent elsewhere if adequate accommodation for advanced cases were available. As regards early diagnosis, it is held that little further advance can be made unless by routine examination of the general population, as is now done for school children, and even by treating more cases on strong presumptive evidence without actual proof of tuberculosis. As to methods of treatment, "ultra-violet radiation and heliotherapy have not in general experience proved of any definite help in treating pulmonary tuberculosis and have in some cases increased the activity of the disease. In two of the Board's institutions a test of the value of light radiations is now being undertaken." General health is regarded as playing a larger part in recovery than the amount of lung involved, but the extent of lung damaged, and the presence or absence of tubercle bacilli in the sputum, have much to do with the permanence, or otherwise, of recovery. "There is no improvement to report in the proportion of patients who are admitted to the hospitals for advanced cases only which they are within sight of death. Over 25 per cent of all deaths occur within four weeks of admission."

Dr. Fowler of Pinewood Sanatorium contributes "a non-statistical review of the results of sanatorium treatment," in which he makes shrewd and pungent comments on various matters, holding that incomplete rest may sometimes produce a useful citizen, while another individual, under complete rest, may become "a numskull he'llth fiddist." He says "a sanatorium full of consumptive patients who are well trained is a safer place than the average railway carriage or cinema house" with promiscuous expectation. Much may be done in educating patients against undue alarm from hæmoptysis, and in the control of desire to cough until the ciliated epithelium has accumulated sputum for easy expectoration. Dr. Agriss of Highwood Hospital for Children says that it is now becoming known that tuberculous children can be taught to expectorate. Also, in early cases, huskiness of voice in the majority may be the only symptom. Dr. Douglas Potter of the King George V Sanatorium discusses the value of "angiolymphic" ad-

vised by Rous of Paris, and concludes that the claims made for it are not borne out by experience. Dr. Whitby of Highwood Hospital for Children has found that some cases of prolonged albuminuria in children were associated with amyloid disease, and gives particulars of four such cases. Mr. W. G. Sutcliffe, F.R.C.S., of Princess Mary's Hospital for Children, Margate, writes on the treatment of tuberculous glands of the neck, he holds that in presence of caserative abscess, sinuses, etc., "radical operative treatment is not only more rapid in effecting a cure but safer, and often less disfiguring than the alternative methods recently advocated." Dr. H. O. West, medical superintendent of the same hospital, gives an account, accompanied by photographs, of the facilities there provided for "sky shine" therapy.

It will be seen from these notes that this supplementary fasciculus contains much that is of interest and importance, both to specialists and to general practitioners.

Correspondence.

REGISTRATION OF OSTEOPATHS

SIR,—I am as anxious as any of my colleagues can be to curtail the influence of unqualified practitioners, as osteopaths and chiropractors at present are, but I do not think the attitude of mere derision assumed by some medical men is best suited to achieve that purpose.

It is precisely because the osteopaths in their practice, as distinct from their theory, have stumbled upon a real therapeutic truth that they have in some instances achieved success where orthodox medicine may have failed. Let me explain my meaning.

The methods actually practised by osteopaths are manipulation and pressure of the tissues, chiefly about the spinal column. Those who have lived in the East know what marvels the native masseurs sometimes accomplish, the picture drawn by Kipling of the restoration of him who moribund from fatigue is recognized as a true reflection of facts by all who know the East, and although the technique of these wretchedly educated American masseurs is compared with the technique evolved by the immemorial cult of Eastern massage "as is moonlight unto sunlight," there still remains a modicum of value in it. And there is, as it happens, increasing scientific evidence to show that certain disordered conditions (of which very little is known) of the tissues produce symptoms seldom ascribed to their proper cause, and capable of being advantageously modified by pressure and massage. The observer who has advanced the farthest in this field is Dr. Hubert Higgins, who founded his research on long anatomical study—he was for thirteen years demonstrator of anatomy in the Medical School of Cambridge University. His paper published in the *Medical Press and Circular*, May 11th, 1921, contained the first sketch of this new theory, but it was completely ignored by the medical profession in this country.

Briefly the theory is this. The cell under certain noxious influences (such as poison, fatigue, etc.) takes up water with a force which is very remarkable. The researches of Fischer and his beautiful experiments prove this property of the cell very conclusively. The swollen cells produce a condition which Fischer calls cellular oedema, which Higgins has named "localized lymphatic stasis." Tissues made up of swollen cells present to the palpating finger sensations of resistance, which may vary in degree from a gelatinous softness to an indurated-like hardness. These changes take place especially likely to take place in parts of the body (1) where movement is restricted, or (2) space is confined. As an example of the first condition the lower part of the spine may be given, and of the second condition the space between the atlas and the skull. The states of tissue may be modified by skilled application of pressure and manipulation, and unfortunately a very high degree of anatomical knowledge is postulated for the best application of such therapeutic measures, especially about the atlas.

The presence of foci of bacterial infection and the consequent toxæmia would explain very many cases of these changes in the tissues. The osteopaths, who know nothing

of bacteriology and therefore affect to condemn it, have thus missed the very first principle of their pretended craft. The bacterial cause should obviously be eliminated first, but the manipulative measures are also exceedingly valuable, and it is my firm conviction that it is because osteopaths occasionally, and without knowledge of what they are doing, actually perform these therapeutic exercises that they achieve their successes, the reality of which it is merely foolish to doubt.

More recently some important observations have been carried out in Paris under the inspiration of Professor Jean Sicard. It has been conclusively proved that in these cases of stasis, when there is resulting pressure upon important nervous tissues—as, for example, when the peritoneal fat is impeded—the operation of luminectomy has been successful in relieving symptoms. In some cases these scars have given definite shadow in ray photographs, and Professor Sicard has discovered a preparation known as lipiodol which exerts an influence in cellular restoration when injected into affected tissues.

My own attention was drawn by the work of Higgins to the possibilities of alopecia being caused by these lymphatic stases, and I contributed a short paper at the last meeting of the British Association of Dermatologists in which I recorded my observations during the past four years upon such cases of alopecia associated with focal sepsis. It is impossible in a letter to elaborate this argument further, but I wish to say very emphatically that in my opinion a case has been made out for further investigation of the remedial effects of manipulative movements, dictated by skilled anatomical knowledge, about the spine and neck.

The sterility of the osteopathic theory cannot better be exemplified than by the reflection that since the origin of the cult in 1873 its disciples have not added a halfpenny's worth of investigation or knowledge to the subject. Their methods are confined to the meiest "rule of thumb" practice from which no advance can be expected.

It is surely time that the profession began to clean up problems which undoubtedly await solution in this department of practice, and should avoid the reproach of remaining ignorant of measures which undoubtedly may be valuable. There is no person who registered practitioners should not very speedily acquire a technique in advance of that practised by the osteopaths and should obtain even better results.

Now I would add some comments on the actual position of the burning question of registration of unqualified osteopaths. They have secured a very considerable following in the House of Commons itself, and it must not be forgotten that causes are lost and won in the House of Commons by the counting of votes. Unless it bestirs itself the profession may wake up any morning to find that it is encumbered with strange and unwelcome bedfellows on the *Medical Register*. Unhappily there is considerable distrust of the opposition of the medical profession to this registration—opposition which is supposed to be dictated by self-interest. For the profession is an unorganized corporate body to enter the lists I think would be undesirable, but the exercise of personal influence on their local members of Parliament by doctors throughout the country would be a very valuable method of attack. I hope that the profession will realize that danger is imminent, and that it will not cherish any foolish hope which I see expressed in a letter from one of your correspondents this week, that the movement will die of its own inertia.—I am, etc.,

London W. Oct 26th

F. GRAY LITTLE

and only seven, colleges of osteopathy in America which have been officially described by the Board of Regents of the State of New York in accredited institutions.

The British Osteopathic Association is trying to obtain some sort of official register of qualified osteopaths in order that the public may be protected from unqualified osteopathic impostors. You are right when you say, "Doubtless a large number of osteopaths differ very little from the chiropractors", on the other hand, there are registered medical men practising chiropractic in London. The establishment of a register of osteopaths would help to clean up the mess.

It is significant in itself that many inquiries from medical friends as to the nature of osteopathy have been addressed to Sir H. J. Waring. He is, as his address indicates, well qualified to point out the disadvantages and dangers of osteopathy. He is not qualified to tell them of the advantages and results to be gained from its employment. From what source, may I ask, did he obtain his osteopathic knowledge?

We stand on the fact that "the impairment of the circulation which prevents the so-called elements or vital materials being properly supplied to the different parts and organs" is an important cause of disease, not, as stated, the cause of disease. Therefore, of course, we osteopaths differ from the chiropractors. Our manual manipulations are not of "the supposed diseased parts," but of the structural abnormalities of the body.

Sir H. J. Waring states that "in a narrower terminology osteopathy assumes that all diseases are due to an osteopathic lesion, these lesions being in connexion with the ligaments or joints of the spinal column." This is quite a fair remark. That narrower terminology is chiropractic, which he confuses with osteopathy—with an obvious purpose.

I admit that the term "subluxation" has been used very extensively by practitioners of osteopathy to express a slight irregularity in position in the spinal column. It should not be used, and is not used, by modern and educated osteopaths.

It is stated in the address that "osteopathic lesions may or may not be shown by palpation, inspection, or ray investigation." I submit that osteopathic lesions are *always* shown by palpation and are corroborated generally by inspection and frequently by a ray examination. Osteopathic lesions, in the widest sense of the term (that is, soft tissue framework abnormalities included with the bony lesion) are found in all diseases. If they have not pre-existed the disease and caused or helped to cause it they are reflexly produced through the intervention of the related spinal cord segment when an organ is attacked by an efficient organism or if an organ is directly functionally abused. If Sir H. J. Waring will read *Symptoms and their Interpretation*, by the late Sir James Mackenzie, he will the more readily understand the above. He will find, in *Symptoms of Visceral Disease* (Pottenger) "the distribution of visceral nerve offers a path through which stimuli from the peripheral nervous system may influence the viscera and through which visceral stimuli may influence peripheral structures."

The site of the osteopathic lesion naturally varies according to the locality of the disease, the vasomotor and other nerves mostly but not entirely, belonging to the autonomic nervous system largely determining this. The nature of the affection naturally has little or no influence on the exact site of the lesion. Hence it follows that the would-be scathing remarks about "osteopathic pathology" rather miss the mark. No educated osteopath maintains that all disease is the result of pressure upon nerves as they emerge from the spinal canal. This theory is absurd, but it must be admitted that it was taught in the very early osteopathic schools and is taught in all the chiropractic schools to-day.

Diseased conditions of the eye and the ear are successfully treated by osteopaths. This surprises Sir H. J. Waring as he states that "the nerves of these organs are not given off from the spinal cord." The somatic nerves and the nerves of special sense to those organs are not given off from the spinal cord. But the all-important vasomotor nerves to the eye and the ear do pass through

Sir—Your leading article (BRITISH MEDICAL JOURNAL, October 17th p. 708) on osteopathy, chiropractic and medicine is so much fuller and so much more knowledgeable than the address on that subject delivered before the Medical Society of London by Sir H. J. Waring that perhaps you will allow me to reply to the latter.

You point out that "osteopathy is progressive" and that "there are two distinct cults" whereas Sir H. J. Waring mixes up qualified osteopaths with what he would call, other falls. There is a British Osteopathic Association which admits to its membership only qualified osteopaths. A qualified osteopath is a person holding a D.O. degree from an approved college of osteopathy. There are seven,

the spinal canal and its foramina in some part of their course from their origin in the preganglionic cell in the central nervous system to their destination in the muscle wall of the blood vessels of the eye and ear. This explains how osteopathy has cured many a case of deafness and many a case of blindness and will cure many more. Has he forgotten that the sympathetic fibres going to the blood vessels of the eye come from Budge's centre in the spinal cord (C7 to D3), and has he forgotten that the superior cervical ganglion, which he in close anatomical relationship to the transverse processes of the second, third, and fourth cervical vertebrae, innervate the blood vessels of the head?

The reason that it is difficult to get evidence of osteopathic lesions from trained x-ray medical experts are three

1 Osteopathic lesions are so commonly found that the trained x-ray expert regards them as being within the realms of normality or, at any rate the average condition.

2 The average osteopathic lesion is not so gross as a subluxation in the medical sense of the term. In the usual osteopathic vertebral bony lesion two bones are more or less fixed at the extreme of a normal relationship. An osteopathic lesion is more of a joint fixation than a subluxation.

3 Even trained x-ray experts are prone to pronounce a spinal column normal unless they can find a definite subluxation, a dislocation, a fracture, a tubercular or some such gross structural abnormality. Individual fixed vertebral deviations are normal.

I agree with all that Sir H. J. Waring has to say about the many other cults that have sprung from osteopathy, but the way he mixes up osteopathy with narpapathy is clever but definitely misleading, to say the least of it. He is not only misleading but is inaccurate in what he has to say about osteopathic colleges in America. It is sufficient in answer to him to state that the Board of Regents of the State of New York made an official investigation of all the colleges in the United States, and, as a result, in the official reports of the State of New York on Higher Education in Medicine for the past twelve years they have placed the seven colleges of osteopathy, which are members of the Associated Colleges of Osteopathy, as duly accredited institutions. No student can obtain a D.O. degree at any of these osteopathic colleges in less time than four years, not eighteen months as erroneously stated by Sir H. J. Waring. If he were to pay a visit to the American School of Osteopathy at Kirksville he would find there up to date osteopathic hospitals, good dissecting rooms, elaborate laboratories, and an adequate staff of whole-time teachers and everything that is required to turn the 800 enthusiastic students there into well educated modern osteopathic practitioners.

I am sure it is true that cases are on record where an appendicæ abscess has ruptured while the patient has been under the care of an osteopathic physician, and I am equally sure that there have been many cases where an eminent surgeon, such as Sir Holburt Waring, has been called in consultation to a case of acute abdominal pain, has with the experienced hand, and has found the abdomen full of pus on his next urgent examination, on the best of us are liable to make mistakes in the diagnosis of malignant disease and tuberculosis.

One reason why the average general medical practitioner is afraid to do what the osteopath does in a case where it is obvious that adhesions should be broken down, is that he is so concerned with organs and drugs and germs and the knife that he has not time to study the framework of the human body as it deserves to be studied.

Dr E. Graham Little, M.P., said in the discussion that "there were cases in which osteopaths, quite unwittingly had done a considerable amount of good to the patient under their treatment." I resent the words "quite unwittingly." Since I have spent two years in America, and have also returned later for post-graduate instruction which I found most up to date and valuable and since I have devoted all my professional thoughts and studies since 1910 to the problems under discussion, I repeat I resent the words "quite unwittingly" when I, by spinal adjustment alone, cure a case of bilateral neuritis which has baffled many more experienced and learned medical men than I am.

You say that "Whether he [the qualified osteopath] believes in his doctrine is a matter for his own conscience." I have consulted my conscience, and can honestly and sincerely say that I believe in our doctrine. I retain the name of osteopathy. I do so out of loyalty to my osteopathic teachers. I really do not think, with all due deference to you, Sir, that it is the name that draws it. The work that counts. Lastly, I do not think that Dr Morris Fishbein, author of *The Medical Follies* is an impartial judge. For years he has been after the blood of the osteopaths. It is part of his official work to do so.

You rightly advise medical practitioners, in their own interests, to make themselves acquainted with the details of osteopathy. I will guarantee to find in London, Birmingham, Manchester, Liverpool, Newcastle, Edinburgh, Glasgow, and Belfast, members of the British Osteopathic Association who will acquaint any medical man who is sincerely interested with the details of osteopathy. Personally I am ready and willing to treat any reasonable number of test cases, provided they are not all what might be called "medical-snags," and provided the medical investigators are not too hopelessly biased against osteopathy. I am sure that most, if not all, of the members of the British Osteopathic Association are equally willing to submit to the same test in order to show the efficacy of osteopathy and in order to justify the belief that is in them. I doubt if you will find a member of the British Osteopathic Association accepting for treatment an operable case of cancer, or if you will find him or her manipulating a tuberculous joint in its acute stages, or if you will find him promising to cure an advanced organic nervous disease.

The members of the British Osteopathic Association are not asking for the privilege of signing death or birth certificates, they do not have to sue for fees, they do not want to prescribe dangerous drugs, and they have never been prosecuted for malpraxis—I am, etc.,

W. KELMAN MACDONALD,

Edinburgh, Oct 26th

MD Edin DO

SIR,—While admiring the robust attitude of Sir H. J. Waring in exposing osteopaths and their kind, and agreeing with his suggestions in so far as they make for either the educational elevation or, preferably, the extermination of such cults (*BRITISH MEDICAL JOURNAL*, October 17th, p 679), he but tapped tentatively an important nail on the head in implying that the medical profession is itself to blame considerably for the success of quacks. He says, "The public is always dissatisfied with a doubtful diagnosis given by a physician or surgeon, and of his inability to explain the nature of a disease in a few words, and also with a definite remedy." Whence such "doubt," "inability," and lack of "definite remedy"? Their source must account for so many patients drifting to quacks. I have never known anyone consult a quack who had not previously sampled orthodox doctors, usually many. It is my firm belief that the success of the quack is largely contributed to by the general lack of scientific knowledge of human psychology, psychopathology, and psychotherapy in our own profession. Were every doctor to give to these fascinating subjects a modicum of the interest and energy he bestows upon the study of organic disease, the quack would be deprived of his main asset—the psychoneurotic patient. It needs but superficial observation to see that the majority of those who eventually resort to quackery of all descriptions are, to some degree, of abnormal mentality, often mental sufferers deserving of our keen attention and sympathy. Were doctors to resort to the following routine with every patient, and thereby include the quack-drifting type, they would hear of fewer wanderings from their fold.

1 While listening attentively to the complete list of complaints endeavour to form an idea of the patient's conception of the nature and origin of his condition, he often suppresses it.

2 Employ a thorough systemic, organic examination, paying particular attention to the system the patient conceives to be at fault.

3 Then definitely tell the patient whether organic disease sufficient to account for the symptoms has been

found or not, ordering definite and appropriate treatment if found

4 In the event of no considerable organic disease being discovered it is most desirable that the doctor should then be equally capable of (a) eliciting psychoneurotic symptoms, which experience will show to be the rule in the seekers of advice for supposititious organic disease (b) convincing the patient that such symptoms are abnormal and that they and the apparently organic symptoms both rest upon a common basis—a mental one, (c) prescribing and administering psychotherapy as definitely as he would other treatment in the case of organic disease

This routine is not idealistic if the public learns to expect it and learns that there are none of us who may not need special help at one or more of its stages, or extensions of time for its completion. It may seem uneconomical, but in reality would cost the public less money than at present pours into the coffers of quacks and is paid for quick remedies. When we do justice to the fullness and diversity of our own combined professional knowledge the quack will perish from inanition, he is no more vulnerable to it than to legal enactments. Let us remember that all potential quack-drifters feel ill, and are so mentally or bodily. It is intolerable to them to be told "there is nothing the matter," and insult added in a bottle of medicine. Like flies they flit from doctor to doctor, let us see to our own inducements to keeping them out of the parlours of conning spiders—I am, etc.,

London W 1 Oct. 19th

THE SURGICAL TREATMENT OF MITRAL STENOSIS

SIR—I have read with the greatest interest Mr. Souttar's description (October 3rd, p. 603) of his operation for the relief of mitral stenosis. It shows triumphantly the necessity of the interior of the left auricle, and of its passage of communication with the ventricle, to surgical measures.

My object in writing is to draw attention to a danger which must attend an operation such as that described, but to which no reference is made either by Mr. Souttar or your correspondents Messrs. Strickland Goodall and L. C. Rogers and Dr. Martin O. Raven (October 17th, p. 722). The danger arises from the fact that these cases of pronounced mitral stenosis are so often the seat of recurrent attacks of acute endocarditis (Mr. Souttar's case was admitted with pain in the limbs, though the temperature is not recorded). In such cases fresh vegetations are a common pathological feature, and the risk of the detachment of these in passing the finger through the auriculo-ventricular orifice, with embolism as a necessary consequence is plain. I need not dilate upon this peril, which even very delicate manipulation might involve. Was the finger guarded by the rubber glove (I do not find mention of this detail)? I ask because it seems to me that it should be unguarded since the most delicate tactile sensibility is needed.

Mr. Souttar seems very wisely to have refrained from a large section in this case, but when he decided to "limit intervention to such dilatation as could be carried out with the finger," it will, I think, strike most observers that the mere pressing of the finger, even if some force were used, could never leave any appreciable effect in the minor degrees of mitral stenosis, and that nothing but section could serve in every case of "button-hole" mitral—I am, etc.,

London W 1 Oct 19th

HARRINGTON STANSBURY

SIR—The interest taken in Mr. Souttar's account of his operation on a case of rheumatic carditis, when he stretched the stenosed mitral orifice with his finger (BRITISH MEDICAL JOURNAL October 3rd p. 603) is not surprising. What is remarkable is that it has taken such a number of years before "mitralotomy" has been seriously attempted. The old method of treatment in a paper published in the *Lancet* of April 2nd 1893 (p. 927), entitled "Cardiac pericarditis: its nature and effects," I there pointed out that the distance of the stenosed and incompetent mitral orifice (until cardiac breakdown) is partly

valvular, and partly due to the auricular systole overlapping the ventricular. I concluded the article with these words

"I am thankful to have been led to believe that the aortic and mitral valves have acquired their positions of rest before the support, in the one case of the ventricle, and in the other of the auricle is withdrawn from them. I can understand also how a stenosed and incompetent mitral valve may be present and regurgitation with its accompanying systolic murmur be absent as is so frequently found, since the auricle itself by its prolonged contraction in these cases defends the orifice and I anticipate that with the progress of cardiac surgery some of the severest cases of mitral stenosis will be relieved by slightly notching the mitral orifice, and trusting to the auricle to continue its defence."

The progress of cardiac surgery has been slower than I then anticipated, but if the present attempts to surgically enlarge a stenosed mitral orifice be not too severe or applied too late (that is, when the auricle is already exhausted and commencing to dilate, and unable when contracting to become small), the incompetence of the mitral valve would not entail the regurgitation one might expect, for the left auricle is the great defender against regurgitation in these cases—I am, etc.,

INFECTED MYOMA COMPLICATING PREGNANCY

SIR,—The letter from Mr. Arthur Crook (October 24th, p. 768) emphasizes the point I raised in my *Tumours complicating Pregnancy*, etc.—namely, the desirability of diagnosing the presence and nature of infection before performing conservative operations on the pregnant uterus containing myoma.

According to my information bacteriological examination is as yet unreliable for a rapid diagnosis. In the case of obstructing myoma reported (as also in the case infected with *Bacillus Welchii*) there were no clinical indications of infection. The decision to remove the uterus instead of performing myomectomy was made for the following reasons:

(1) The frequency with which degeneration occurs in these cases—in my experience 5 out of 6. Degenerated tumours are especially liable to infection.

(2) The frequency with which infection is found on bacteriological examination—in at least 2 out of 6 cases.

(3) The greater safety of total abdominal hysterectomy, especially in the case of obstructing fibroids—in 26 collected cases 2 deaths, of which one was due to the attempted myomectomy by an exceptionally skilful operator, the late Dr. Haultain—I am, etc.,

HERBERT R. SPENCER

London W 1 Oct 24th

LEFT-HANDEDNESS

SIR,—I have read with much pleasure and interest your annotation on left-handedness (October 3rd, p. 620), but I have not yet seen any comments on it in spite of your request that "my new light on its cause or significance is very welcome." I am induced to offer an observation made by me and which has been confirmed by a long association with child-life. It is that all normal children up to the fourth year of life use the left hand by preference. In testing this rule must be taken by the observer that no suggestion is made to the child that the right hand should come into use. Granting that the observation referred to above is correct—and I hold that it is—Plato, to whom you refer was not far from the truth when he gave to us as his belief that preference is determined by "nursing and education."

The acquisition of two handedness is of great value, both in sport and work. In my opinion it can be achieved by anyone if there is the requisite determination, and if a suitable method is chosen for acquiring it. I found billiards played with the left hand to handicap myself one of the best means to commence the training.

In reference to your remarks on the use of the eye in shooting, may I say that men who have shot for most of their lives are quite aware of the fact that they do not close one eye in alignment of the gun, but always shoot with both eyes open. In partridge driving, with a crossing shot, which is rapid work, I take it that the

gun is aligned by the master eye, which is usually the right, the bird being selected by the left eye, and the "swing forward" by the right or left, in accordance with the direction taken. This is by the way, and has no bearing, I think, on the main question at issue—I am, etc.,
Cheltenham Oct 26th
LEWIS W MARSHALL

MEDICAL WOMEN IN MEDIAEVAL TIMES

SIR,—There will be general agreement with Dr Singer when he writes (BRITISH MEDICAL JOURNAL, October 17th, p 722) that "the time has arrived when wild and undocumented statements concerning medieval medicine should cease to be bandied about." In the efforts made to attain this most desirable consummation Dr Singer has himself played a distinguished part. It is all the more singular, therefore, that some of the statements in his letter are undocumented. No doubt the brevity of his communication, and the feeling which apparently prompted it, may account for this.

I am not referring here to his remarks in regard to the *School of Salerno*, for his views in this respect are already familiar through the writings of Huber, H Haeser, and others. There are, however, some points in his reference to St Hildegard upon which he might usefully shed fuller light.

There can be no doubt that the date of her death is generally set down as 1179. Dr Singer, on the other hand, says that she "was alive and in fairly vigorous health at that date." Passing over the question of her health and the adjective that may best describe it, one would be glad to learn what is the true date and the grounds upon which it is substantiated.

In the next paragraph Dr Singer writes as follows: "It would perhaps be needlessly harsh to recall the fact that the life of *Saint Hildegard* was not altogether saintly, were it not that the Roman Catholic Church, to which she adhered with greater vehemence than orthodoxy, has itself promulgated this conclusion." To me, at least, the logic of this statement is somewhat at fault. The lives of historical personages are matters of history, and it would be a perversion of history to present a picture in which the virtues only and none of the failings are depicted. But if it is harshness to mention vices it is not very clear why that harshness is removed if someone else appears to act in accordance with that view. This, however, by the way. One thing is quite certain—namely, that the contemporaries of St Hildegard had a higher regard for her character than Dr Singer has. She was looked upon as a saint, and her feast is still observed in the diocese of Mainz and perhaps elsewhere in Germany. She even finds a place in the Roman Breviary. All this, however, does not necessarily mean that she has been proclaimed a saint by the Roman Catholic Church.

This is not the place to enter into the history of canonization. It is enough to say that in early times local opinion was often the only basis for a cultus. During the lifetime of St Hildegard the indiscretions of local favour led the Popes to decree that the virtues of persons proposed for public veneration must be examined by councils under their presidency. And such has been the practice since. The Venerable Bede was known by that title from the end of the eighth century, but as a matter of fact the formal canonization only took place in 1899. Dr Singer holds that something similar has happened in the case of St Hildegard. His use of the technical term "promulgated" permits of no other interpretation. Now although on several occasions the preliminary investigations have been initiated in her regard, I was not aware that they ever bore definite fruit. I am sure that other students will share my desire that Dr Singer should give us the date on which the decree of her canonization was promulgated—I am, etc.,

"PREVENTION OF RHEUMATISM" AND INFLUENZA

SIR,—Dr E H Wilkins, in your issue of September 19th (p 542), remarks that English writers' recommendations to the avoidance of cold and wet amount to very little. My personal experience of influenza and rheumatism may throw some light on the discussion.

I have had over twenty attacks of influenza two a year generally about December and February—the wet months. I tried all kinds of vaccines from stock to autogenous and found them useless. For several years I had fibrositis with effusion in both knees, easy in summer bad in winter. Misfortune at last stimulated my dull wits and having failed to find any make of leather boot capable of ensuring a dry foot I took to goloshes wearing them even when the pavements were slightly damp from fog. My attacks of influenza ceased. Immunity began to grow, and on a bright day, accompanied by muddy pavements I left my heavy goloshes at home. When I had finished my visits I put on fresh stockings and boots and hoped nothing would happen. Five days later I had to go to bed with a temperature. I have never trusted leather since. My pulse has recovered its strength and regularity, my rheumatism has disappeared, my health is restored, and I require less clothing. Neither drugs nor vaccines accomplished what an absolutely dry foot did.

The prosperous days during the late war induced the Lancashire people to discard their wooden clogs in favour of leather boots, the predicted epidemics of pneumonia and influenza followed. Pasteur failed to infect the domestic fowl with anthrax until he chilled its feet, surely the analogy holds with regard to influenza germs and chilled feet in human beings.

Rubber boots and shoes, exactly like ordinary laced boots and shoes, are now procurable, they are comfortable and easy to walk in, and no heavier than an ordinary boot or shoe—I am, etc.,

London, S W 6 Sept 20th

J FLETCHER

VENEREAL DISEASE IN THE NAVY

SIR,—The letter in your issue of October 3rd (p 629) from a "civilian clinical officer" condemning unhealed naval medical officers is to be regretted.

Having been condemned in general terms "on the obvious failure of the naval medical authorities to enforce observance of prophylactic precautions against venereal diseases," I will now make my defence without dwelling on the obvious retort that they have no power of enforcing it.

Many years ago Sir James Porter introduced sound methods for the prevention of venereal disease. A silver preparation was used for the prevention of gonorrhoea and calomel for the prevention of syphilis.

In recent years the issue of the silver preparation has been discontinued. Various excuses have been given for this, but during my efforts to get it reintroduced I came to the conclusion that an unfavourable report on the silver salt then in use had been welcomed by economists at the Admiralty. Departmental economy appears to be the real reason for its abandonment, with the resulting increase of gonorrhoea on such stations where alternative methods are difficult of application.

Both calomel and silver appear to act on the tubes supplied to the Admiralty. It was in order to avoid this that Messrs Ferris and Co kindly supplied me with samples put up, at my suggestion, in gelatine "oucles." Some of these were forwarded to the Admiralty, but did not meet with an enthusiastic reception, and then I was placed on the retired list, so the matter dropped.

The real solution would appear to be for the Admiralty to give the Medical Department sanction to issue efficient outfits at cost price to the canteens, where they could be purchased by the men—I am, etc.,

OPPORTUNITY IN THE SERVICES FOR RESEARCH

SIR,—I was much interested in the report in the JOURNAL of October 17th (p 711) of the admirable presidential address by Sir William Lishman to the War Section of the Royal Society of Medicine on October 12th. With the subject-matter of the address all officers, past and present, of the R A M C will cordially agree. That such opportunities exist there can be no doubt, a proof of which statement is to be found in the brilliant work of Sir William Lishman himself in the realms of original research. But what of the conditions? Sir William does well to draw attention to the fact that, in these days of "diminished personnel," the present time does not seem quite appropriate for suggesting to overworked officers that they should voluntarily add to their already heavy duties. I agree

At the present time the average officer has no time for research, not only on account of overwork, but because he has a sword of Damocles constantly hanging over his head in the form of the eternal uncertainty of his stay in any one station in which he may happen to be. The lot of the present-day officer is 'here to-day and gone to-morrow'.

There is the added uncertainty of his future as regards promotion, pay, and pension. He has seen regulations, expressly framed to accelerate promotion, flagrantly violated. His pay and pension are still unstabilized, and are liable to reduction at fixed intervals.

These are not the conditions, nor is this the atmosphere, best suited for the encouragement of private study or original research. The above facts may be, in the words of Sir William Lushman, only "a temporary phase of depression," but the sooner steps are taken to remove the depression the better. If we are honest with ourselves we must realize that, so long as the "depression" lasts the "further outlook" for original research in the R.A.M.C. is, in the words of the weather forecast, extremely "uncertain" to say the least of it—I am, etc.,

October 21st

SCRUTATOR

Obituary

DR A G JENNER, medical officer of health for Stockport, died suddenly on October 5th, aged 40. He received his medical education at the University of Liverpool, and took the diplomas of M.R.C.S. Eng. and L.R.C.P. Lond. in 1907 and the D.P.H. Liverp. in 1911. After serving as house-surgeon and senior house-physician to the Royal Southern Hospital, Liverpool, he became resident medical officer to the West Derby Union Infirmary, and for two years subsequently served as resident medical officer to the Park Hill Fever Hospital of the Liverpool Corporation. In 1912 he became assistant medical officer, assistant tuberculosis officer, and assistant school medical officer for Burton-on-Trent, where he remained till his appointment in 1913 to be district tuberculosis officer to the Harrogate area. In July, in August, 1914, he proceeded to Stockport to take up the duties of tuberculosis officer, and was appointed deputy medical officer of health in 1915. On the departure of Dr Smeeth, the then chairman of the health committee, and Dr Corbin, medical officer of health, for active service with the forces Dr Jenner had charge of the health of Stockport under the health committee. In 1917 Dr Jenner joined the R.A.M.C. with a temporary commission, and for two years served on the administrative staff of the Salonica Army and had charge of the 98th and 131st Sanitary Sections with the rank of captain. On his return to Stockport in May 1919, he was appointed special disease officer, and in February, 1922, succeeded the late Dr Corbin as medical officer of health for the borough. He was a member of the Stockport, Macclesfield and East Cheshire Division of the British Medical Association.

We regret to record the death of Dr THOMAS CUNNINGHAM of Kilbarchan, as the result of a street accident in Paisley on October 20th. Dr Cunningham received his medical education in Glasgow, London, and Dublin, obtaining the M.B. Ch.B. degrees of Glasgow University in 1900. After holding appointments in the fever hospitals in Glasgow and the Maternity Hospital, Dublin, he began general practice in Kilbarchan in 1906, he was appointed medical officer to the parish council three years ago. Dr Cunningham took an active interest in National Health Insurance and was a member of the Renfrewshire Panel Committee from its origin. In 1921 he became medical secretary to the Committee which appointment he held until his death. On several occasions he represented the Committee at panel conferences in London. In 1920 he was appointed by the Scottish Board of Health as a member of the County Insurance Committee. He was a member of the British Medical Association.

Dr AUGUSTE LUTAUD who founded the *Journal de Médecine de Paris* in 1880 has recently died at the age of 76, as the result of an automobile accident.

Universities and Colleges

VICTORIA UNIVERSITY OF MANCHESTER

Mr C. J. POLSON M.B., Ch.B. Birm., has been appointed demonstrator in pathology.

Entrance scholarships in medicine have been awarded to G. L. Brown and L. Loulds.

Travelling Fellowship in Psychological Medicine

Through the generosity of Mr Ernest A. Knight, honorary treasurer of the University of Manchester a selected medical graduate will be enabled this winter to visit the United States. His mission will be to study and eventually to report upon the methods used in approved institutions to investigate the part played by mental factors in the development, treatment and cure of mental disorders. Should the University so desire, he will be required on his return to deliver an address on the subject of his investigation. The competition was open to those who had obtained or had entered upon a course for the diploma in psychological medicine of the University. It is hoped to announce the award at an early date. The purpose of the fellowship is that of the Knight Prize which is offered annually in the University to encourage the study of psychological factors in the causation and cure of mental disturbances.

NATIONAL UNIVERSITY OF IRELAND

The Senate at its meeting on October 23rd made the following decisions:—
Studentships (Pathology):
E. McDermott, 1st; J. J. O'Connell, 2nd; J. J. O'Connell, 3rd.
Dr Henry Hutchinson, 1st; J. J. O'Connell, 2nd; J. J. O'Connell, 3rd.
(2) Physiology: Patrick Keane, 1st; Dr and Mrs W. J. Browne, 2nd; Gold Medal and Prize: Gold medal Ellen Power, prize not awarded.

Dr Robert P. Larnan was appointed to the professorship of midwifery and gynaecology at University College Dublin.

The Senate decided that a special final medical examination should be held in January 1926 in the University Colleges of Dublin, Cork and Galway, provided that not fewer than seventy-five candidates enter and pay the special entry fee of £5 on or before November 12th, 1925.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At the meeting of the Royal College of Surgeons of Edinburgh held on October 21st Dr Arthur Logan Turner was elected president for the ensuing year. Sir David Wallace C.M.G. vice-president and Mr Alexander Miles, LL.D., F.R.C.S. Ed. secretary and treasurer.

Mr David Middleton Gray, F.R.C.S. Ed. Edinburgh, was awarded the Lister Victoria Jubilee Prize of £100 in recognition of his contributions to practical surgery and surgical pathology.

The following 28 successful candidates, out of 61 entered at the Fellowship examination between July 6th and 13th, were admitted Fellows:

J. C. Anderson, J. R. S. G. Beard, J. M. Black, C. R. Childs, B. M. Dicl, C. S. L. Hall, R. L. Galloway, J. Goldberg, R. Grant, J. D. Grierson, Dorothy W. Hall, F. J. S. Hall, O. M. Irwin, H. W. Johnston, Valda Loun, J. C. L. Lumsden, W. J. Macdonald, H. J. Malkin, S. M. M. J. Moore, C. H. M. M. A. R. Richards, J. H. Robert, R. C. Shackleton, J. H. Shaw, V. Sourasky, D. B. Whitlock, A. C. H. Yates.

The diploma of licentiate was granted to E. W. Johnson.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the annual meeting of the President and Fellows of the Royal College of Physicians of Ireland held on October 19th the following officers were elected:—President, Dr Thomas Henry Wilson; Vice-President, Dr W. A. Winter; Treasurer, Dr Bewley; Registrar, Dr T. P. C. Kirkpatrick; Censors (medicine) Drs Nesbitt and Rowlette (medical jurisprudence and hygiene) Dr Winter (midwifery) Dr Fitzgibbon.

Dr Jane Elizabeth Waterston was elected a Fellow of the College.

Sir John Moore was re-elected the representative of the College on the General Medical Council.

The Services

DEATHS IN THE SERVICES

Brigade Surgeon Lieutenant-Colonel Selim Myer Salaman Bombay Medical Service (ret.) died in London on September 19th, aged 81. He was born on October 7th 1843, the son of Morris Salaman of Dublin and educated at Trinity College Dublin where he graduated as B.A. in 1865 as M.B. and Ch.B. in 1866 and as M.D. in 1869. Entering the Indian Medical Service as assistant surgeon on April 1st 1869, he became brigade surgeon lieutenant-colonel on April 16th 1895, and retired on March 31st 1895.

Brigade Surgeon Richard Hamilton Batty Bombay Medical Service (ret.) died at Newham on September 1st, aged 84. He was born in July 1841 at Leeds the son of the late Arthur H. Batty of Rogerstown House, Ardee, Ireland. After taking the L.R.C.S.I. in 1863 and the L.S.A. in 1866, he entered the Indian Medical Service as assistant surgeon on April 1st 1867 and became surgeon-major after twelve years' service retiring with a step of honorary rank on June 24th 1887. He served in the Abyssinian war in 1867-68 (medal) in Afghanistan in 1878-80 (medal) and in Burma in 1886-87 (medal with clasp).

Medical News.

THE Schorstein Memorial Lecture will be delivered in the Anatomical Theatre of the London Hospital by Sir Humphry Rolleston, Bart., F.R.C.P., on Friday, December 4th, at 4.15 p.m., the subject selected is lymphadenoma. Members of the medical profession are cordially invited.

PROFESSOR L. P. CANNICATT will deliver Chadwick Public Lectures at Reading on October 30th and 31st, his subject being the nature and composition of food and its relation to the energy needs of the body. Dr. William J. Howarth will lecture for the Chadwick Trust in London on October 30th and November 6th on the control of the food supply. The remaining Chadwick Lectures in London deal with insects in relation to public health, by Sir Wilfred Beveridge, at the Royal Society of Medicine on November 18th; sanitary provisions of the new Public Health Act, 1925, by Mr. Alexander Macdonald, K.C., at the Royal Institute of British Architects, on November 26th, and encephalitis lethargica in England, by Dr. A. S. McNalty, at the Royal Society of Medicine, on December 9th.

At the meeting of the Medical Officers of Schools Association to be held at 11 Chandos Street, London, W.1, on Friday, November 6th, at 4.45 p.m., Dr. A. I. Simey will read a paper on the prophylaxis of the common cold and febrile catarrhs.

As already announced, the annual dinner of Fellows and Members of Sections of the Royal Society of Medicine will be held on Thursday, November 19th, at 8 p.m., at the Hotel Victoria, Northumberland Avenue. The Right Hon. Neville Chamberlain, Minister of Health, will be present, and during the evening the Jenner medal will be presented to Dr. S. Monckton Copeman, F.R.S.

THE annual dinner of the Cambridge Graduates' Club of St. Bartholomew's Hospital will take place on Tuesday, November 24th, at 7.30 p.m., in the King Edward VII Rooms, Hotel Victoria, with Mr. L. B. Rawling (Cams) in the chair. The price of the dinner is 12s. 6d., the honorary secretaries are Dr. H. N. Burroughes and Mr. Reginald M. Vick.

THE West Riding Association of Graduates of the Edinburgh University will hold its annual dinner at the Great Northern Hotel, Leeds, on Wednesday, November 18th, at 7.15 p.m. Mr. Alexander Miles will be the guest of the association. The dinner will be preceded by a general meeting at 6.30. Any graduate desiring information is asked to apply to the Honorary Secretary, 35, Manor Row, Bradford.

Two post graduate courses were arranged during September by the Joint Tuberculosis Council in consultation with the Ministry of Health. A course of two weeks in the pathology and bacteriology of tuberculosis was held by Dr. Roodbousio Glyone, at the City of London Hospital for Diseases of the Heart and Lungs, and another course in non-pulmonary tuberculosis, lasting one week, included demonstrations at various hospitals. The courses were well attended, and the council intends to arrange post graduate courses in 1926, the syllabus of which will be issued in January.

THE programme of lectures and discussions to be held during the coming session of the Child Study Society of London has now been received. Among the papers to be read are one by Mr. Maudslayi Yearsley, F.R.C.S., on "The development of speech in the normal child," on November 12th, and another on "The teaching of shorthand as part of a general education," by Dr. R. Langdon Down, on December 10th. Ordinary meetings are held at the Royal Sanitary Institute, 90 Buckingham Palace Road, S.W., at 6 p.m. On January 4th, 1926, a conference of educational associations will be held at University College Gower Street, at 5 p.m.

THE Fellowship of Medicine announces that Dr. Campbell McClure will lecture for it on November 2nd, at 5.30 p.m., in the lecture hall of the Medical Society of London, on the climatic treatment of tuberculosis, all members of the medical profession will be welcome. Throughout November the London Local Hospital will hold a course in venereal disease if there is a sufficient entry. There will be a three weeks course in gynaecology at the Chelsea Hospital for Women from November 2nd to 21st, and from November 3rd to 23rd Dr. Porter Phillips and Dr. T. Beaton will give twice weekly lecture demonstrations on psychological medicine at the Bethlem Hospital. At the Victoria Park Hospital a course will be held in diseases of the chest from November 9th to 21st. From November 23rd to December 12th the Royal Waterloo Hospital will hold a course in the diseases of women and children. A late afternoon course (4.30 to 6) will be held at the London Temperance Hospital from November 23rd to December 4th for the benefit of general practitioners. Copies of each syllabus of these courses and of the general programme may be obtained from the Secretary, 1, Wimpole Street, W.1.

THE Royal Society of Arts begins its 172nd session on Wednesday, November 4th, at 8.30 p.m., when Sir Thomas H. Holland, K.C.S.I., K.C.I.E., F.R.S., chairman of the council, will give an inaugural address on the organization of scientific research throughout the Empire.

THE Chelsea Clinical Society held its annual dinner on October 20th, when the president, Dr. Seymour Price, who was in the chair, was supported by the presidents of the Medical Society of London, the Hygienic Society, the West London Medical-Chirurgical Society, and the Master of the Society of Apothecaries, Sir Holburt Waring, president of the Medical Society of London proposing the toast of "The Chelsea Clinical Society," referred briefly to its long history and its great present value. He urged the necessity of medical practitioners taking more interest in municipal affairs as well as in legislation. More medical members of the House of Commons were required because health should receive greater attention in the future than had been the case previously. Dr. Seymour Price, in reply, announced that future meetings of the society would be held in the board room of St. George's Hospital and two of the meetings would each be preceded by a dinner. The subjects to be dealt with during the coming year included treatment by insulin, deep x-ray and radium, heliotherapy, spas, endocrine extracts, and the treatment of late syphilis. Mr. Ivor Back proposed the health of "The Visitors in a witty speech, and Dr. T. Vincent Dickinson, Master of the Society of Apothecaries, in his reply alluded to the quarrels at the end of the seventeenth century between his society and the Royal College of Physicians with regard to the dispensing of prescriptions, which were brought to an end by the Apothecaries Act of 1815. The toast of "The President" was proposed by the treasurer, Dr. K. L. Eckenstein.

DR. FRANCIS HARE has resigned the office of medical superintendent of the Beckenham branch of the Norwood Sanatorium for the Treatment of Inebriety and Drug Addiction owing to ill health. His place at the Mansion, Beckenham Park will be taken by Dr. A. W. George, who has been acting as assistant at Roudlesham Hall, the Suffolk branch of the sanatorium, patients receive similar treatment, and have the advantages of a park of 450 acres.

THE library of the Royal Society of Medicine will, on and after November 3rd, be open on two evenings of the week (Tuesdays and Fridays) until 10 p.m.

A CONFERENCE on social insurance in its national and international aspects is to be held under the auspices of the League of Nations Union from November 23rd to 26th at the London School of Economics. The following aspects of the problem will be discussed: the Government pensions scheme, the unification of social insurance, health insurance, workmen's compensation and accident prevention, unemployment insurance, family insurance, and the international aspects of social insurance. Further particulars can be obtained from the Secretary, League of Nations Union, 15, Grosvenor Crescent, S.W.1.

A CONGRESS of odontology will be held from November 24th to 30th in Moscow, and both medical practitioners and dentists are invited. Further particulars may be obtained from the organizing bureau, Narkomsdrav, Zubchist, Moscow.

A COURSE in pulmonary radiology with practical demonstrations will be held at Leysin from November 3rd to 7th, under the direction of Dr. Jaquerod and M. Lauffenburger, radiologist to the climatic station of Leysin. Further information can be obtained from M. Lucien Emery, Grand Hotel, Leysin.

A STUDENTSHIP in cancer research, on either the physiological or the chemical side, has been founded at the University of London by Miss L. S. Gibbs in memory of her mother. It will be called the Laura de Schiceto Studentship and will be of the annual value of £150.

THE recent Esperanto Congress at Geneva included a medical section which was well attended by medical practitioners from various countries. It was decided to found an international medical journal under the editorship of Professor Vanverts of Lille.

DR. PIERRE NOLF, professor at the University of Liège, has succeeded the late Dr. Depage as president of the Belgian Red Cross.

A CHAIR of otorhinolaryngology has been founded at the Toulouse Faculty of Medicine, with Dr. Escart as its first occupant.

THE nineteenth international post graduate course at Vienna, from November 23rd to December 6th, will deal with syphilis and dermatology, with special reference to treatment. It will be followed by a practical course in internal medicine, lasting for twelve days, from December 7th. Tickets for the course may be obtained from Professor Richard Wasicky, Bureau der Wiener Aerztekurse, Schlüsselgasse 22, Wien VIII.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the **JOURNAL** should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861 9862, 9863, and 9864** (internal exchange four lines).

The **TELEGRAPHIC ADDRESSES** are

MEDICAL SECRETARY, Medicine Westcent London

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams **Bacillus Dublin** telephone 4737 Dublin) and of the Scottish Office 6 Drumsheugh Gardens, Edinburgh (telegrams **Associate Edinburgh** telephone 4361 Central).

QUERIES AND ANSWERS

COCKROACHES

THE medical superintendent of a country hospital asks how to rid the building of cockroaches by which it is at present overrun.

MUCOUS STOOLS

"L G" (London) asks for suggestions for treatment of the following case. For many years the stools have been moist and semi solid but are sometimes fluid. They usually contain much mucus and are very sticky, there is no putrefactive smell. The patient is receiving a mixed diet including both brown and white bread. Previous treatments include enemas both simple and containing a bismuth suspension, intestinal disinfectants, bismuth and tannic acid preparations by the month, also paraffin and agar preparations and tincture of opium. The opium given in 5 minim doses by the month, is effective, but leads to constipation.

INCOME TAX

Cash Basis

"T H A" has been told that he is liable not merely on the cash receipt basis, but on his profits calculated from cash receipts plus increase in book debts during the year plus one tenth of the total debts outstanding at the commencement of the year.

As we have agreed before, the cash basis is not strictly correct year by year though it works out satisfactorily in the long run and in view of its obvious convenience inspectors seldom raise any objection to it unless there are abnormal circumstances in the practice which render it inequitable. Assuming that it must be discarded in the present case we have two comments to make on the inspector's basis. (1) The ascertainment of the value of book debts is often a difficult matter, and for the purpose regard should be had to the proportion of debts recovered in previous years. (2) We do not agree that past debts should be brought into assessment, tax was paid as for the years in which those debts became due on the assessments made on the usual basis and there appears to be no reason to think that those assessments were incorrect. The inspector cannot have it both ways if the correct basis of receipt be the value of book debts for the year he cannot claim to include therein receipts for earlier years.

Depreciation of Car Basis of Allowance

"W M H" bought a car in 1921 and is claiming a depreciation allowance for the year 1925-26. The inspector of taxes informs him that the allowance must be calculated on the value of the car as written down by the application of the percentage—which in fact was not allowed—for the period to December 31st 1924.

This is strictly correct but "W M H" should bear in mind that when the cost of renewing the car is incurred the expense of replacement—excluding any element for improvement—less the allowances actually made, can be claimed as a professional expense.

Cost of Is:tant

"C G R" last April took an assistant to live in and is informed that no claim to deduct that expense can yet be made. He asks whether this is correct.

Yes. The expense differs only in degree from any other expense of conducting a practice and is deductible not from the average profits of the past three years but in arriving at the

respective profits of those years. As "C G R" says it may work out unfairly sometimes, but of course that observation applies generally to the system of the three years' average though sometimes it works the other way—as, for instance, when receipts are expanding.

LETTERS NOTES ETC

THE Editor of the *Medical Who's Who* asks us to request all practitioners who have not done so to return their forms with particulars immediately to 8, Stone Buildings, Lincoln's Inn.

A BATH CHAIR is needed for the epileptic daughter of a medical man. Offers should be addressed to the Secretary of the Royal Medical Benevolent Fund, 11 Chandos Street, Cavendish Square, W 1 who states that the case is deserving.

BLACK TONGUE

"T G" (London) writes in answer to Dr Morrison's inquiry about black tongue (October 10th p 678) referring him to a note in the *JOURNAL* of May 3rd 1924 (p 833) where attention was drawn to a section in *Diseases of the Tongue* by Butler and Spence (1900 p 145). The treatment there recommended was to assure the patient that this condition was a mere curiosity and that if active measures were deemed necessary, then painting the tongue with a 2 per cent solution of salicylic acid might be tried, or rubbing in a solution of carbolic acid diluted 1 in 67 with a soft piece of rag, three or four times a day. Lactic acid is also said to be useful.

RAW PANCREAS IN DIABETES

DR BIRKMORE (Chesh) p HAY, Staffordshire writes with reference to the therapeutic value of raw pancreas by the mouth in diabetes mellitus to warn prescribers that some, or most butchers supply the thymus if asked for sweetbread. On consulting *Catell's Dictionary* Dr Birkmore found that the sweetbread was defined as thymus gland or pancreas.

"We are under the impression that this possible source of error has been mentioned before and there is we think, evidence in the letters and notes published that those practitioners who prescribed raw pancreas took care that this gland was supplied and not the thymus."

A LARGE RENAL CALCULUS

DR W A YOUNG, Director, Gold Coast Medical Research Institute (Accra) writes. A native patient was brought into the Gold Coast Hospital, Accra, in a comatose condition, and died shortly after admission.

Post mortem examination revealed that both kidneys were enlarged and lobulated. Incision showed a thin layer of lumen tissue, varying from a quarter to half an inch in thickness, surrounding pus. The ureters were on an average half to three quarters of an inch in diameter and their wall very thin. The bladder was contracted over a hard mass a mixed phosphatic calculus. The bladder wall was just under half an inch in thickness. The weight and dimensions of the calculus were as follows:

Weight	4 oz 265 grains or 131 grams
Length	6.3 cm or 2.45 inches
Breadth	5.6 cm or 2.2 inches
Thickness	4.4 cm or 1.75 inches
Volume	73.9 cc
Circumference	18.9 cm or 7.4 inches

This is certainly a large calculus and it is doubtful if one so large has been reported from the West Coast of Africa before. Jeffrey and Maxwell in *Diseases of China* report one case where the calculus weighed just over 5 ounces (151 grams). The amazing thing, however, was that the man survived so long on such a small amount of renal tissue. It is difficult to say what the origin of the calculus was. There were no signs of schistosomiasis.

In the Museum of the Royal College of Surgeons of England three of the largest calculi are:

(1) A calculus composed of mixed phosphates, weighing 44 ounces (tray weight) which was removed after the death of the patient Sir James Dule published an account of it in the *Transactions of the Royal Society* 1809 p 303.

(2) A calculus of similar composition weighing 34½ ounces removed during life by Mr H M N Milton at the Kasr el Aini Hospital, Cairo from an Egyptian, aged 60. This was described in the *Lancet* 1893, vol 11, p 687.

(3) A calculus weighing 31½ ounces and composed of urates with a phosphatic encrustation. This was also removed during life from an Egyptian at the Kasr el Aini Hospital, and was presented by Dr Owen Richards in 1909.

Among large calculi reported in the literature is one of 22 ounces described by Captain H Smith, I M S, *Indian Medical Gazette* January 1901, p 15.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges and of vacant resident and other appointments at hospitals will be found at pages 35, 36, 37, 40 and 41 of our advertisement columns and advertisements as to partnerships, assistantships and locumtenencies at pages 38 and 39.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at pages 149 and 160.

ON FAITH IN LIGATURES

THE WILLIAM MITCHELL BANKS MEMORIAL LECTURE,
DELIVERED AT LIVERPOOL ON NOVEMBER 5THBY
SIR JOHN BLAND-SUTTON, Bt.,
PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

A WONDERFUL thing in a wonderful world is the healing of wounds. For centuries men troubled themselves very little about what seemed a simple and natural process. The spontaneous healing of simple incised wounds is so common that surgeons were not much concerned with the means by which wounds healed, but were grievously disturbed when wounds they made designedly took more time to heal than those made accidentally. This sort of thing perplexed them.

A mower fell upon a scythe and laid his knee joint freely open. He went to a surgery for treatment. In three weeks the wound healed and he was able to move again. On the same day that the mower cut his knee a swineherd received a punctured wound of the knee joint from the tusk of a boar. He was treated by the same surgeon and in the same time. He died in a few days from acute pyaemia.

Thoughtful surgeons devoted much time and study to discover the manner in which wounds healed. The arrest of bleeding was a source of anxiety. Festerings, the usual sequence of an operation, was not only expected, but its occurrence was promoted by the application of poultices. In England and many parts of the world, civilized as well as uncivilized, a particular virtue attached to cow-dung. I have seen festerings in a woman's breast, a whitlow in a man's finger, and an abscess in a horse's foot, treated with cow-dung poultices. The Mahratta then cattle after the operation a woman smears the back of the breast with cow-dung for luck! In India cow-dung is as much valued for poultices as for fuel, with the additional advantage that the sanctity of the cow adds prestige to the cataplasm. Until the middle of the nineteenth century the surgical treatment of mankind was little better than that in vogue for horses, cattle, cats, and dogs.

Threads of Fate. Ligatures and Sutures

The prime occupation of a surgeon is the treatment of wounds made by accident, or by the surgeon himself in the course of his occupation. The most obvious sign of a wound is bleeding. Surgeons are concerned with the arrest of bleeding and closure of wounds with sutures. The strict apposition of divided tissues promotes healing. The first aim in the treatment of a wound is to stop bleeding. Then to free the wound from foreign bodies. The oozing of blood may be checked by the application of pressure, moderate heat, or styptics. When Machaon, a famous surgeon in the Trojan war, was wounded in the shoulder by an arrow shot by Paris there was much consternation among the Grecian commanders,

And great Machaon wounded in his tent
Now waits that succour which so oft he lent
Patroclus went to his assistance, he removed the arrow-head, washed the wound, infused a styptic, and closed the wound to stop the bleeding. No modern surgeon could do more. In consequence,
The closing flesh that instant ceased to glow,
The wound to torture and the blood to flow.

When blood vessels above the dimensions of capillaries are divided, partially or completely, pressure and styptics are not reliable methods. It is necessary to tie the ends of the divided vessels. The material used for such a purpose is called a ligature. It is a foreign body, and unless properly cleaned is inimical to the union of the wound. The material employed to close a wound is called a stitch, or suture.

In the surgical treatment of incised wounds the methods and material used by surgeons are those of cobblers and tailors—sewing with thread and needle. Tailors and cobblers cut cloth and pelts into suitable shapes and rejoin them with thread and needle to make clothes. Surgeons cut or torn by accident or design. There is no material used by tailor or cobbler which has not been of service to surgeons for stitching wounds.

Plants, insects, and animals have been ransacked for suture material. The long tendons of the limbs and tails of mammals and legs of birds have been used from time immemorial for sewing pelts to be worn as clothes and for stitching wounds. Sewing is an ancient art. The tailor-bird with its bill spins a thread and sews the edges of adjacent leaves together and makes a recess for its nest (Fig 1). This little bird may have taught Adam and Eve the art of sewing "bird smooth leaves together" in order to hide their nakedness. Spiders may have taught our first parents the art of spinning. Indeed, the tribes in West Africa attribute the discovery of weaving to a great hunter who watched a spider making a web for catching flies. They regard the white man as a great spider because he supplies spinnings of cotton (Major Kingsley).

Primitive man makes holes for his threads with a thorn or a sharp fish-bone. When he obtained metal he fashioned an awl, and by making a link near the tip of the awl he invented a needle. Papuans make awl needles out of sharp fish bones, and with strands of fibre they continue to sew pieces of bark cloth very neatly together. It is by no means improbable that tendon was the first sewing material used by primitive man for closing wounds.

Fig 1—Tailor bird and nest

improbable that tendon was the first sewing material used by primitive man for closing wounds.

The Mandibles of Ants as Clips for Wounds

In regions of the world as far apart as India, Brazil and Asia Minor the mandibles of ants have been used from remote times as clips for securing the edges of wounds. Middleton describes the method of using them in Smyrna. The edges of the wound are pressed together and the ant applied by means of forceps. The ant separates its mandibles widely for defence and as the insect is brought to the wound it seizes the edges and remains fixed. The body of the ant is divided with scissors leaving the mandibles grasping the edges of the wound. In a week the wound is healed and the heads of the ants are removed. A wound rather more than an inch in length requires ten of these insects. The mandibles are antiseptic in virtue of formic acid normally present in ants.

Martin Duncan was collecting near Para in 1900. One of the Indians cut himself. Duncan went to the camp for thread and needle to stitch the wound, on returning he found that the Indian had closed the wound neatly and securely with the mandibles of worker-ants (Fig 2).

In Brazil ants are common and more easily obtained than thread and needles. Gudgeon, in a recent article on the subject, shows that this method of fastening wounds

of the skin and intestine was prevalent on the southern and eastern shores of the Mediterranean Sea in 1896. The practice can be traced back three thousand years. A modern modification of this device for holding the skin edges of a wound together is known as Michel's clips.

For many years surgeons have been seeking a reliable material for stitching wounds. Great difficulty besets this apparently trivial matter. In 1804 surgeons in Europe had evolved fifty methods for closing an incision of the abdominal wall. The variations consisted in the number of layers separately united, and the variety of material used for sutures—catgut, tendon, silk, silkworm gut, horsehair, and linen thread, wire—iron, copper, silver, gold, and aluminium. Some ninety and-nine chemical enforcements were recommended to sterilize the suture material. Experience teaches that surgeons have not yet found a perfect material for ligatures and sutures.

No material should be employed that cannot be sterilized by heat without destroying its efficiency.

Catgut prepared from the small intestine of sheep is, with many surgeons, a favourite material for ligatures and sutures. Its popularity is mainly due to the advocacy of Lord Lister. Catgut is a treacherous material, difficult to sterilize, and if thoroughly tanned to ensure freedom from micro-organisms it is as resistant as string. For closing the muscular and fascial layers of an abdominal incision it is especially dangerous. Many cases of wound-burst, post-operative peritonitis, tetanus, and gas gangrene have been reported from its use. The most reliable material for surgical use is silk. It can be obtained of any desirable fineness, even for sewing up wounds of blood vessels. Above all things it can be sterilized by boiling without diminishing its strength. The latest addition to the list of suture material, for special use, is human fascia cut in strips from the patient's own body. We owe this ingenious measure to the skill of W. E. Gallie.

The Fate of Ligatures

The fate of ligatures introduced into the human body in the course of a surgical operation is a matter of great importance to patients and surgeons. In pre-antiseptic days surgeons attributed the sloughing of ligatures to intolerance of living tissues for foreign bodies. In pre-Listerian days it was the practice, in applying a ligature to the end of a divided blood vessel to leave the ends of the thread hanging freely from the wound. Some days after amputation, if the thread failed to separate, we tugged it gently, this interference was often followed by bleeding which not infrequently led to the death of the patient. The standstill of surgery for many centuries was due to the inability of surgeons to appreciate the cause of this difficulty. Lister gave early attention to ligature material, and soon proved that clean ligatures were tolerated by living tissues, but he was much exercised in the choice of material and chose catgut. In a sterile wound a sterile ligature is tolerated indefinitely, it may be encysted by tissues, or disintegrated by leucocytes or wandering cells, and disappear. If septic organisms obtain access to it, local sepsis follows, an abscess is the consequence. The ligature separates and may swim in pus.

The fate of a ligature depends on its situation. Like for example ligatures applied to the pedicle of an ovarian cyst. The thread which embraces the stump of the tube slowly erodes the wall, enters the lumen of the stump, and, being impelled into the uterine cavity, is finally expelled, leaving the free end of the tube neatly sealed and rounded (Fig. 3). It is not uncommon after a simple ovariectomy

for the patient to complain, sometimes for many weeks, of vague pains in the neighbourhood of the pedicle. Careful study of these stumps in recurrent operations teaches that the piece of silk on the arteries and veins of the pedicle may become encysted, and in the course of years disintegrated. Frequently the pedicle adheres to the intestine—ileum, colon, rectum, caecum, or appendix. When the patient escapes intestinal obstruction the loops of thread

are discharged into the bowel and escape. I have witnessed a ligature of this kind travelling along the vermiform appendix to the caecum. Ligatures of many kinds used in operations on the pelvic viscera erode their way into the bladder. A thread of any kind may form the nucleus of a calculus. Urologists tell us that festoons formed by ligatures of this kind are attractive features in cystoscopic demonstrations. I have recovered a loop of silk, unchanged under the serious covering of the caecum, nineteen years after removal of the appendix. Tedious convalescence attended with obscure pains after pelvic operations is due to the discomforts set up by ligatures sealing the nucleus of escape through the walls of hollow viscera. After nephrectomy a ligature on a ureter will erode this duct, be propelled into the bladder, and produce the clinical signs of a migratory renal calculus. The fate of ligatures and sutures used in operations on the

intestines is instructive. When two segments of intestine are rejoined, the divided ends are sutured in layers—mucous membrane and muscle to mucous membrane and muscle. The serous coats are also carefully sutured to each other. An exudation of lymph solder the serous coats with amazing quickness, and the lymph organizes into reparative tissue—if the opposed parts and the ligatures are sterile. The mucous and muscular coats do not unite so quickly, and the sutures slowly slough into the lumen of the gut, where they sometimes hang as loops for many weeks or months.

If it were not for the rapid union of the serous surfaces of the gut, intestinal junctions made by surgeons would rarely be successful, because septic infection from the interior of the bowel prevents immediate union of the mucous and muscular coats. Leakage of the bowel contents into the peritoneal cavity leads to failure and often to fatal peritonitis.

Some of the routes used by ligatures are almost fabulous. One of the most remarkable I found in an American journal. A patient had the spleen removed, and the operation was followed by a left-sided empyema. Some weeks later blood and pus escaped through the trachea. Finally the patient spat up a complicated ligature. This was followed by recovery.

The common route of escape for ligatures is through the operation wound.

The importance of reliable ligatures, reliable in tenacity and in cleanliness, may be expressed in this way:

The hangman's frame — it hangs on a strong rope.
The surgeon's frame — it hangs on a thin thread,
A rotten rope — it is the culprit's hope,
A slipping thread — it is the surgeon's dread.
Py loose knots and ligatures which are soiled
Surgical operations are oft foiled.

Nature's Method

Already I have said the healing of wounds is a wonderful process. To day surgery deals with injured and diseased organs, even the heart and main blood vessels, with astonishing results. The coarseness of surgical methods is obvious when compared with the exquisite union seen in the natural fusions of tissues which occur in natural life.

Fig. 2—Worker ant showing the mandible widely open (from a photograph by Martin Duncan)

Fig. 3—Stump of a Fallopiian tube

In a healthy mother the foetus is developed under perfect aseptic conditions

How wonderful are the exquisite mouldings, fusions, and unions, partial or complete, of the various tubular organs which make up the circulatory system and the alimentary canal. Embryology resembles plastic art; organs are moulded, formed, and re-formed with the same facility as the potter moulds plastic clay. The union of wounds is only an extension of the same process. Nature, in making an animal, does not always succeed in obtaining complete union of the nose, eyelids, cheeks, lips, or abdominal wall. Noses are occasionally double (Fig 4) and bifid (Fig 5) in boys and girls as well as dogs, and oftener. The potter casts aside his pieces in disdain if faulty in outline, crooked in spout, or asymmetrical. Unlike the potter, Nature does not always cast aside the pots she makes in making. Few human beings are as strictly symmetrical as cups and jugs. Surgeons take pride in mending hare-lips, cleft palates, or trimming redundant pieces, removing supernumerary digits and limbs. Even with extreme care in technical detail union of wounds promoted by art is never so neat as pre-natal union of parts, and always leaves a detectable scar at the site of the union. The cleverest tailor or furrier cannot join cloth to cloth or pelt to pelt without leaving a seam. A deft surgeon cannot sew up a wound in the skin without leaving a tell-tale scar. Nature cannot completely close the abdomen after birth without leaving a seam; the omphalos serves as a sign of her incompetency in this matter.

Why, in pre-natal life does union of parts take place so perfectly, and after birth the union of a wound is permanently indicated by a tell-tale scar? It is due to sepsis and disrespect for tissue. The first wound is caused by the sloughing of the stump of the umbilical cord, the navel is the most conspicuous scar in the human body, and the degree of its conspicuousness depends on the degree of sepsis. Before the importance of strict cleanliness was appreciated by doctors and midwives, the simple and universal operation of applying a thread tightly round the navel-string was followed by an appalling mortality. This simple ligature is truly a thread of fate.

Gloves

The wearing of sterilized rubber gloves when operating is the greatest improvement in surgery since Lister discovered the cause of sepsis. It is not only an insurance against infection, but promotes careful handling of living tissues, which are delicate and resentful, especially viscera. Gloves also protect the surgeon against infection from the patient. The human element predominates in

FIG 5—Bifid nose

FIG 4—Girl, aged 3, with a double nose (Souttar)

energy—sharp clean needles of sizes to suit the job, thread of proper fineness and strength, knots tied accurately and neatly. Intestinal, uterine, and cardiac sutures—the latest additions to our craft made possible by Listerian principles—require delicacy, skill, and accuracy for success. The junctions must not only be water tight, but gas tight, immediate union, the essential for success, can only be ensured by a strict aseptic technique.

A simple method of tying the uterine arteries, instead of constructing the neck of the uterus with ligatures, was introduced by Briet of Philadelphia in 1892. This simple method transformed hysterectomy for fibroids from one of the most dangerous operations in surgery to one of the safest.

In surgery, clumsiness with aseptic precautions often ends in success, leaving dexterity associated with laxity in the application of Lister's principles grievously disappointed. Dexterity associated with asepsis invariably wins. The great advance in abdominal surgery since 1880 is a consequence of the improvements in the preparation and choice of ligature and suture material. The method of tying divided blood vessels was introduced by Paire in the sixteenth century, but the dangers of dirty ligatures were not realized until the middle of the nineteenth century. Knowledge of the fate of ligatures was much advanced when Metchnikoff discovered the defensive mechanism of the cell elements of the blood. Surgeons still require a reliable ligature.

Manual dexterity in any trade can only be acquired by much practice. Skill is necessary even in the application of a ligature or a suture, but especially the ligature.

Knots and Digital Clumsiness

In surgery, as in all arts and crafts, the human element has to be taken into account. To watch a woman sewing neatly, quickly threading the needle, tying knots securely and surely, has a fascination all its own. The same is true of tailors, cobblers, and sailors: needles and awls suited to the job, the needles passed in and out at regular intervals, apparently without effort, makes sewing seem simple. A surgeon rarely sews with the same simplicity as a sewing-maid. He does not tie knots with the same certainty as sailors. Many surgeons fumble over knots, yet it is a matter of importance. A slipping ligature or a slack suture has on many occasions led to death. To insert sutures regularly and tie them sufficiently tight to prevent them slipping, and not so tight as to strangle the included tissue, requires much practice. I have watched surgeons critically for many years, and have seen some who rarely tie a knot satisfactorily.

Digital clumsiness is as much a defect as colour blindness, but more obvious.

The evil consequences of loose knots are outdone by the malevolent influence of dirty ligatures and sutures. It is common observation to watch children on their way to school stopping and stooping to fasten a loose shoe-string. Post-operative haemorrhage due to a loose knot is a common

FIG 6—A loose shoe string

surgery as in all affairs of life. The tolerance of animal bodies to physical insults is remarkable. If it were otherwise surgery could not be successful. One man will sew up a wound with coarse thread and needle as if he were sewing sailcloth or sackcloth. It is delightful to watch a dexterous surgeon sew together the edges of an incised wound with a minimum of

event familiar to every house-surgeon, hence the surgeon's lament

My fingers ache with tying many knots
On exting tendon, silk and linen threads,
And examining patients in their coats
Or stitching wounds in faces, limbs and heads
A shipping ligature might disgrace me
Filling a recent wound with ugly clot
And filling my mind with anything but glee,
By bringing the patient to a state of shock
Perchance I might commit felo de se,
Even be drawn into a court of law
And rather than count failure don't you see
It would be wise to close the surgery door
For many patients in these busy days
Though glad to be healed are too shy to praise

Faith in Dressings

The last appanage of an operation which surgeons will discard is dressings. It is a curious tradition that wounds require dressings and bandages. In civilized life it has become a cult to supply, roll, and apply bandages to wounded friends or foes. In uncivilized countries bandages are ill understood. Papuan surgeons, when assisting explorers, cut themselves with European axes and knives before they learnt the sharpness of such tools. Their wounds healed quickly with ordinary clean methods, although the Papuans took off the bandages and used them for personal adornment (Wollaston).

In our domestic life it is usual to apply a linen rag, the softer the better, to a cut, its cleanliness was secondary to its softness. The carpenter, when he cuts himself at work, takes a thin shaving of wood, dips it in warm glue, and seals the wound. The carver and gilder in similar circumstances applies a strip of gold-beater's skin, this is made from the caecum of the ox. The farm labourer applies a plug of chewed tobacco to check bleeding, sometimes a cobweb. Primitive man binds up his wounds with leaves, blades of grass, or bast. Surgeons formerly used adhesive plaster. When bacteriology entered the swarms of disease-provoking germs in the surrounding human habitations surgeons turned then with to devise means for excluding them from wounds. This idea loomed in their minds. Motes dancing in the air are dear to poets but inimical to successful surgery. Lister endeavoured to render air in the vicinity of the operating area germ-free by impregnating it with chemical vapour. The skin area concerned in the operation was treated with an antiseptic to make it germ-free. After the operation it was swathed in expensive, clumsy, and uncomfortable dressings and bandages. Antiseptics are powerless to destroy bacteria in living tissues. Realizing the discomforts of surgical dressings for wounds, and the inability of excluding air from operation wounds, I have for the last ten years abandoned dressings for dry wounds. By this I mean wounds where there is no leakage of blood, serum, saliva, cerebro spinal fluid, bile, urine, pus, or faeces.

Where drainage is unnecessary, dressings are unnecessary. Once daily the line of incision and the sutures are smeared lightly with tincture of iodine, or a similar antiseptic, and left exposed to air, or merely in contact with clean underclothes. The results are excellent—the wound heals rapidly, safely, and soundly with minimum discomfort and minimum expense.

It is important to keep bacteria out of a wound. Surgeons know that the methods employed in bacteriological rooms for sterilizing apparatus are ideal for the operating room—the application of heat by boiling or baking, all instruments, dabs, sutures, and ligatures are sterilized by heat. The hardest lesson came last. The most dangerous agents in the performance of an operation were the unseen hands of the surgeon and his assistants. An uncontrollable factor in an operation is the pre-existing sepsis in the patient. Pasteur's influence is not limited by the recognition of the microscopic agents of disease. His laboratory methods revolutionized surgical technique as well as those of the winepress, distillery, dairy, and sewage farm. In spite of all advances operative surgery remains a simple craft. It is impossible to estimate how much greater would have been the sum of human happiness if surgeons had appreciated the value of simple cleanliness in their operative work and in the simple matter of keeping clean their hands.

A lecture on modern surgical technique appropriately ends with a Listerian doxology. It is undeniable that the edifice of aseptic surgery rests on a solid foundation, it is a glorious inheritance and Lister's greatest monument.

THE CHEMOTHERAPY OF LOCAL SUPPURATION ACRIFLAVINE AND BORIC ACID COMPARED

BY

J. G. GRAHAM, M.B., CH.B.,

LATE CASUALTY OFFICER, OUT-PATIENT DEPARTMENT WESTERN INFIRMARY, GLASGOW

ATTEMPTS to assess the therapeutic value of an antiseptic in individual cases of pyogenic infections in the human subject seem seldom to yield conclusive results. There are, of course, two main reasons for this—first, the complication introduced by operative procedures, and secondly, the absence of an adequate control. As regards operative procedures, the treatment frequently involves incisions and excisions—that is, measures which are calculated usually to expedite the onset of the stage of healing, and which, therefore, obscure the effect to be ascribed to the antiseptic. Again, the fact that the same patient does not as a rule present simultaneously separate, but similar, lesions which are suited for treatment with different agents, robs the experiment of a necessary control. When such a control is lacking we are deprived of essential information as to how the individual is behaving at the time when exposed to pyogenic organisms, and therefore cannot exclude the possibility that the case would have followed a similar course under other treatment. It is the want of such controls which necessitates recourse to general comparisons, based on the experience gained from several large series of cases treated by different agents, when attempting to determine the value of a new therapeutic procedure. But satisfactory statistical evidence of this kind appears to be difficult to acquire, as may be judged from the conflicting conclusions which are reached by different observers. Accordingly, even in a single case, such as the following, which supplies this element of controlled observation, seems to be worth recording.

A woman aged 35, received an extensive burn from boiling fat on the back of the right hand and forearm. At three areas the burning was severe the whole depth of the epithelium being destroyed. Two of these areas were on the forearm, and measured respectively slightly over and under 1½ inches in diameter, the third was on the hand and had a slightly greater extent (1½ inches in diameter), but was the least severe as it was distinctly shallower than the other two. The whole burned part was to begin with, treated with moist dressings soaked in 1 in 1000 acriflavine solution applied first of all within about an hour after the injury had been received. This treatment was continued for two days, after this granulation tissue was present in the base of all three deep areas, there was no suppuration and the patient felt little discomfort. At this stage the treatment of the hand was changed, wet boric lint being employed the forearm continued to be treated with watery acriflavine solution but the strength was reduced to 1 in 5000. The dressings were renewed once daily. Two days later the lesions on the forearm showed healing in progress with ingrowth of epithelium at the margins and a small amount of serous exudate from the granulating surfaces*. In contrast to these the area on the back of the hand was painful epithelial ingrowth was wanting, and there was seropurulent discharge from the surface. Four days later at the parts treated with acriflavine healing was advancing and there was complete absence of sepsis now the area on the hand was extremely painful and was actively suppurating. Thereafter in the interest of the patient the use of boric acid was given up and the hand was like the arm treated with wet dressings of acriflavine 1 in 5000. Three days later the burned area on the hand had ceased to suppurate pain was gone and healing was in progress. After a further period of five days healing was complete in all the areas.

* Bennett, Blacklock and Browning have dealt with the process of healing under acriflavine treatment (BRITISH MEDICAL JOURNAL August 19th 1922)

British Medical Association.

Lady BARRITT, CBE, MD, MS, President

DISCUSSION ON
THE TREATMENT OF INOPERABLE CANCER OF
THE FEMALE PELVIC ORGANS

OPENING PAPERS

I—JAMES HEYMAN, MD,
Radium Hemmet, Stockholm

ONLY about ten years ago the treatment of an inoperable cancer of the female pelvic organs was a very unsatisfactory undertaking, and we had very limited possibilities of relieving the great sufferings of our patients by palliative means. Curetting and thermo cauterization, cauterization with zinc chloride, sulphuric acid, formalin, and so on, treatment by means of acetone, and the ligaturing of the vessels of the uterus, were the methods used in different combinations. It is not to be denied that some considerable palliative results were achieved by these methods, but the improvement of the symptoms was of short duration and a lasting benefit was very rare. Nor did these methods arouse any great interest, and most surgeons would seem to have taken up a purely negative attitude as regards the treatment of an inoperable uterine cancer. "Inoperable" in those days was synonymous with "incurable."

The radiological treatment of cancer has from its very first appearance attracted keen interest. Even if the very great expectations which this treatment at first aroused have not been realized, yet radiological treatment as a palliative method has so thoroughly taken the place of all others, that nowadays treatment of inoperable cancer of the female pelvic organs practically means radiological treatment. It seems to me probable that the Gynaecological Section of the British Medical Association has inserted in its programme for this congress the question of the treatment of inoperable cancer of the female pelvic organs with a view to its radiological treatment. I have accepted the invitation of your distinguished society to open this discussion in the belief that what would be likely to interest you is our actual experience at the Radium-Hemmet at Stockholm.

A thorough treatment of this subject ought, in my opinion, to include the different forms of uterine cancer, of cancer of the vagina, the urethra, the vulva, and the ovaries, and also cancer of the bladder and the rectum. The last two mentioned diseases are in Sweden more often treated by the general surgeon than by the gynaecologist. Partly owing to this fact, and also on account of my own insufficient experience of these two maladies, I have decided to leave them out. My description of the treatment of inoperable cancer of the uterus, the ovaries, the vagina, the urethra, and the vulva, is founded on the experience of patients suffering from these diseases which we have treated at the Radium Hemmet at Stockholm during the fifteen years of its existence. Before I give an account of our results I want to say a few words about the Radium-Hemmet and the work done there.

The Radium-Hemmet is a hospital especially established for radiological treatment. It was founded by the Swedish Cancer Research Society, and is partly supported by Government grants. It is conducted by Gösta Foissell, who introduced radiological treatment into Sweden, and who has been the leading spirit of the institution since its foundation. The Radium Hemmet receives all cases suitable for radiological treatment. There is a special department for gynaecological cases, and it is only about the work of this

department that I am going to speak. The gynaecological cases are almost without exception referred to us by surgeons or gynaecologists attached to other hospitals or gynaecological clinics.

Foissell has on repeated occasions stated that we should first of all obtain sufficient experience of radiological treatment in the inoperable cases and those localized cases in which an operation is contraindicated. The radiological treatment was to be extended to the operable cases only when the results justified such a procedure. Consequently, it is almost exclusively inoperable cases that are referred to the gynaecological department. Cancer of the cervix is an exception. When, about 1919-20, we presented our first report on five years' results of the radium treatment of carcinoma of the cervix, these results were considered such a strong argument in favour of radium treatment that the leading gynaecologists and surgeons of Sweden ceased operating for carcinoma of the cervix. Since that time we have to a great extent treated even operable carcinomas of the cervix. Thus, with the exception of the cases of cancer of the cervix admitted later than 1920, nearly all the cases referred to us had been considered inoperable by the surgeon who sent in the case.

When a case is received for treatment at the Radium-Hemmet it is at once registered and referred either to the inoperable or to the operable group of cases. Since the different cases are thus doubly controlled by their own medical attendant and by the surgeon in charge at the Radium-Hemmet, different opinions regarding the grouping of the cases are to a certain extent removed. A thorough and minutely organized control of the patients has made it possible for us not to lose sight of a single patient during all these years, thus we can report on 100 per cent of the cases treated. To a great extent this is due to the fact that the Swedish Government pays the travelling expenses of poor patients to and from the Radium Hemmet. In the following notes only those cases are described which have been primarily treated radiologically, recurrences after operation are not included.

I now pass to our results, and will begin with the biggest and without doubt most important group.

Cancer of the Cervix of the Uterus

When we speak of inoperable cases of cancer of the cervix we mean cases in which the glands, the bladder or the rectum will also be involved, or cases in which the tumour is fixed by involvement of the parametrium. Such inoperable cases, in which operation, though technically possible, is contraindicated by complications in other organs, are not included here. Altogether during the years 1914-22 inclusive we have treated 440 cases of inoperable cancer of the cervix, 234 of these cases, during the years 1914-19, have been under observation during at least five years. Here, in accordance with common practice, we can speak of a permanent cure in those cases which have been free from symptoms for at least five years.

Sometimes we notice the most wonderful results in the way of cure by means of the radiological treatment, even in inoperable and apparently hopeless cases of uterine cancer. But we must keep in our mind that in most cases we are only able to produce a palliative result by means of the radiological treatment—that is, the cessation of bleeding, of the discharge from the vagina, and of the pain, together with the recovery of the patient and her ability to work. This striking and important primary result has been often and thoroughly described in radiological literature. I shall not weary you with the repetition of known facts, instead of that I shall try, with the aid of figures, to give you some idea of the degree and the duration of the improvement of symptoms, based on 375 cases of inoperable cancer of the cervix, which have been treated at the Radium Hemmet during the years 1916-22 inclusive. In most of these cases we have detailed records of the improvement of the symptoms. In cases where for some reasons or other our records are incomplete with regard to the last months of the patient's life, I have taken for granted that the improvement of the symptoms had ceased when we last examined the patient. On account of this the numbers indicating the improvement of the symptoms are most probably to be considered too low.

The four following tables show the effect of the radium treatment on bleeding, on the vaginal discharge, on pains, and on the capacity to work, in 375 cases of inoperable cancer of the cervix, primarily treated with radium at the Radium-Hemmet, 1916-1922 inclusive

TABLE I—*Effect of the Radium Treatment on Bleeding*

	Cases	Per cent
Suffered from bleeding at commencement of treatment	342	
Became symptom free	308	90.1
For more than six months		61.7
For more than one year		35.4
For more than two years		23.4
Showed improvement	10	2.9
No improvement	24	7.0

TABLE II—*Effect of Radium Treatment on Vaginal Discharge*

	Cases	Per cent
Suffered from discharge at commencement of treatment	336	
Became symptom free	203	60.4
For more than six months		66.0
For more than one year		46.8
For more than two years		32.0
Showed improvement	82	24.4
For more than six months		20.7
No improvement	51	15.2

TABLE III—*Effect of Radium Treatment on Pains*

	Cases	Per cent
Suffered from pain at commencement of treatment	234	
Became symptom free	125	53.4
For more than six months		53.6
For more than one year		40.0
For more than two years		28.0
Showed improvement	44	18.8
For more than six months		25.0
No improvement	65	27.8

TABLE IV—*Effect of Radium Treatment on the Capacity to Work*

	Cases	Per cent
Became able to work	231	61.6
For more than six months		62.2
For more than one year		45.5
For more than two years		30.3
Remained unable to work	144	38.4

Thus in nearly all the cases bleeding has been stopped for longer or shorter periods. In nearly two-thirds of the cases the vaginal discharge has ceased, and in over 50 per cent the pain has disappeared. The freedom from symptoms has in more than one third of the cases lasted more than one year. The recovery of ability to work is perhaps the best indicator of the palliative results. Table IV shows that two thirds have regained strength to resume work, nearly one-half of these have remained able to work for more than one year, and one-third even for more than two years. It seems to be worth mentioning that only 38.4 per cent of 375 patients with inoperable cancer of the cervix have not temporarily regained strength to resume work, and among these a great number were from the beginning considered hopeless cases.

In certain cases freedom from symptoms has been gained both as regards the subjective and the objective symptoms. These cases are collected in Table V. The figures found

TABLE V—*Inoperable cases of carcinoma of the uterine cervix primarily treated with radium at the Radium Hemmet, 1914-1922 inclusive*

Of	Free from Symptoms after the Lapse of—									
	3 cent	Per cent	1 year	Per cent	2 Years	Per cent	3 Years	Per cent	4 Years	Per cent
440 cases 1914-22	190	43.2	118	26.8	89	20.2				
358 cases 1914-21						64	17.9			
291 cases 1914-20							47	16.5		
244 cases 1914-19								9	3.7	15.7

here indicating cases free from symptoms six months after the commencement of the treatment must be accepted with great reservation. At that time it is often impossible to decide whether small palpable changes depend on cancer or "reaction," and many of them must be considered uncertain. One year after treatment the conclusions are more

certain. We find that one-fourth of our 440 cases from 1914 to 1922 are free from symptoms after the lapse of one year, and one-fifth after the lapse of two years from the commencement of the treatment. In order to judge the result after three years, the cases from 1922 must be left out. This being done, 358 cases remain treated in 1914 to 1921 inclusive, of which 17.9 per cent are free from symptoms after three years.

We find that out of 234 cases from the years 1914 to 1919 39 cases have remained healed for five years or more—that is, 16.7 per cent of permanent cures in these inoperable cases. It is not a very high percentage of cases in which a permanent cure has been obtained, but we must remember that these cases would have been left as hopeless had not the radiological treatment been adopted. These cases of long-standing cure inspire us to fresh exertions in spite of all disappointment. Of our inoperable cases some have been cured for several years, as may be seen from the following list:

- 1 patient has been cured for 11 years and is still alive
- 4 have remained cured for 10 years, and are still alive
- 5 remained cured for 9 years. 3 are still alive, 1 died from diabetes and 1 from an unknown disease
- 4 remained cured for 8 years, and are still alive
- 5 remained cured for 7 years, 4 still live, 1 died from cancer
- 9 remained cured for 6 years. 7 still live, 2 died from cancer

Cancer of the Corpus Uteri

As mentioned above, I did not include in my report on carcinoma of the cervix those clinically inoperable but technically operable cases where it was not the extension of the growth itself which made the case inoperable but complications in other organs. In proportion to the great total number of cases of carcinoma of the cervix these cases are very few and may be left out of account. Regarding cancer of the corpus, we have another state of things. Among the comparatively few inoperable cases of carcinoma of the body these technically operable cases, which, on account of old age and pronounced adiposity, are clinically inoperable or not suitable for operation, form a rather considerable group. For this reason they ought to be dealt with.

At the Radium-Hemmet during the years 1915 to 1922 there have been treated 54 cases of inoperable and technically operable cases of cancer of the body of the uterus. Until 1915 no such cases came under treatment. Of these cases 29 were inoperable. Metastases were present in 10 of these—in 5 cases in the vagina only and in the other 5 in more distant parts. In the remaining 19 cases the surrounding tissues were infiltrated and the uterus fixed, 25 cases were technically operable. Contraindications to an operation were affections of the heart and the lungs, diabetes, old age, and a bad general condition (in 14 of the 25 cases), pronounced adiposity with or without other complications in 11 cases. The results of the treatment are given in Table VI.

TABLE VI—*Technically operable and inoperable cases of cancer of the body of the uterus primarily treated with radium at the Radium Hemmet 1915-1922 inclusive*

Of	Free from Symptoms after the Lapse of—									
	1 Year	Per cent	2 Years	Per cent	3 Years	Per cent	4 Years	Per cent	5 Years	Per cent
54 cases 1915-1922	75	64.8	70	55.6						
37 cases 1915-1921				22	59.5					
27 cases 1915-1920						16	59.3			
17 cases 1915-1919								10	58.7	

The table shows us that of the 17 cases which have been under observation for five years or more (58.7 per cent) remain free from symptoms after five years. But when it becomes possible to judge the five-year results of all the 54 cases, the percentage will be somewhat less. This is already evident for the two-year result for all the 54 cases, which shows 55.6 per cent of all the cases to be free from symptoms after two years.

TABLE VII—Inoperable cases of carcinoma of the body of the uterus primarily treated with radium at the Radium Hemmet, 1916-1922 inclusive

Of	Free from Symptoms after the Lapse of—						
	2 years	Per cent	3 years	Per cent	4 years	Per cent	5 years
29 cases 1916-1922	11	37.9					
21 cases 1916-1921			8	38.0			
11 cases 1916-1920					5	35.7	
9 cases 1916-1919							4

Of the inoperable cases of cancer of the corpus after five years 44.4 per cent were cured. Here, too, when it becomes possible to form a judgement on a larger material, our five-year results will most probably be nearer 30 per cent than 40 per cent.

TABLE VIII—Technically operable cases of carcinoma of the body of the uterus primarily treated with radium at the Radium Hemmet, 1916-1922 inclusive

Of	Free from Symptoms after the Lapse of—						
	2 years	Per cent	3 years	Per cent	4 years	Per cent	5 years
25 cases 1915-1922	19	76.0					
16 cases 1915-1921			14	87.5			
13 cases 1915-1920					11	84.6	
8 cases 1915-1919							6

Of the 8 technically operable cases which have been under observation for five years, 6 patients are still living, which would be 75 per cent. To judge by the two-year figure for all the 25 cases and by the intermediate figures, it seems that the five-year results will only be slightly worse. The worst result has been in the inoperable cases, where there were evident metastases at the very beginning of the treatment. Of these 10 cases only one was alive after four years. In view of the fact that in cases of cancer of the body of the uterus metastases do not occur until after a long period, and that consequently the cases that come in with metastases are far advanced, nothing else, of course, is to be expected.

Of our cases of cancer of the body 1 inoperable case is alive and has been free from symptoms for nine years, 3 technically operable cases are alive and have been free from symptoms for seven years, 1 inoperable case is alive and has been free from symptoms for six years. One patient with a technically operable cancer of the body died some time ago from bronchopneumonia after being free from symptoms for seven years. At the necropsy, which was very carefully performed by our pathologist Dr. Reuterwall, all suspected glands and tissues were microscopically examined, but no trace of cancer could be found anywhere.

Cancer of the Ovaries

The inoperable cases of cancer of the ovaries may, as regards the prognosis with radiological treatment, be divided into two groups. One group contains those cases which I have called the inoperable ones—cases in which operation either has not been tried or has been restricted to an exploratory laparotomy, the other group contains those cases which I have called incompletely operated cases, in which most of the ovarian tumours themselves have been removed, but where it has been necessary to leave the metastases in many cases very extensive ones, in the omentum, the peritoneum, and the abdominal wall.

The results of the treatment of the inoperable cases, as shown in Table IX, are not good. After a lapse of only one year only one-fourth of the cases can be considered free

TABLE IX—Inoperable cases of carcinoma of the ovaries radiologically treated at the Radium Hemmet, 1916-1922 inclusive

Of	Free from Symptoms after the Lapse of—							
	1 Year	Per cent	2 years	Per cent	3 years	Per cent	4 years	Per cent
15 cases 1913-1923	4	26.7						
14 cases 1913-1922			1	7.1				
12 cases 1913-1921					1	8.3		
10 cases 1913-1920							0	0.0

from symptoms. After two years there remains only one case, and after four years no patient survived. Considerably more favourable is the result of the second group (Table X). After the lapse of four years one-fourth of the

TABLE X—Incompletely operated cases of carcinoma of the ovaries radiologically treated at the Radium Hemmet, 1913-1923 inclusive

Of	Free from Symptoms after the Lapse of—							
	1 Year	Per cent	2 years	Per cent	3 years	Per cent	4 years	Per cent
23 cases 1913-1923	10	43.5						
22 cases 1913-1922			8	36.4				
16 cases 1913-1921					5	31.2		
15 cases 1913-1920							4	26.7
14 cases 1913-1919								3

cases are free from symptoms, and after five years 21.4 per cent. The difference in the prognosis induced us some years ago to urge an exploratory laparotomy in every case of inoperable cancer of the ovaries, combined, if possible, with the removal of the ovarian tumour. The radiological treatment should be given as soon as possible after the operation. Of the incompletely operated cases of cancer of the ovaries one has been free from symptoms for ten years and two for nine years.

Cancer of the Vagina

In my account of this disease I include all the 16 cases of primary cancer of the vagina treated during the years 1911 to 1922 inclusive. All have been regarded as inoperable because, even if operation in some cases was technically possible, the prognosis after operation is as a rule considered to be very unfavourable in all cases of vaginal cancer. As regards diagnosis, I have considered as vaginal cancer those cases in which no other primary focus in the genital organs has been found and in which the vaginal portion of the cervix has been macroscopically normal.

Of our 16 patients, 1 has been alive and free from symptoms for three years, another for four years, and 2 cases for more than five years. In the two last mentioned cases the local tumours were the size of a hen's egg.

Cancer of the Urethra

A rare form of tumour is the carcinoma which is limited to the urethra and its nearest surroundings. We have treated 6 such cases at the Radium-Hemmet. Both by means of Roentgen rays only (one case) and radium salt applied direct to the tumour (two cases) only a subjective improvement of short duration has been noted. The treatment seems to have induced an increased tendency to sloughing. A very noticeable decrease of the tumour has occurred in two cases treated with emanation "seeds" (1 mc per square centimetre of the tumour surface). Particularly in one of these cases, where an artificial suprapubic fistula was made before the radium treatment, the result has been very satisfactory. This may be a coincidence. Still, it seems as if the diminished tendency

to sloughing, which we have noticed in this case, has been due to the fact that the urine has been diverted from the tumour, and it seems to me as if it was in consequence of this that the general condition of the patient has improved so quickly. Our experience encourages further attempts in this direction.

Cancer of the Vulva

There are two circumstances that make inoperable cancer of the vulva the most difficult of access for radiological treatment. In the first place, this kind of cancer—a high grade cancer, is often badly infected, and is exposed to constant irritation—as biologically very slightly susceptible to radium. In the second place, the surrounding tissue, owing to its anatomical structure, is extremely sensitive to treatment.

At the Radium-Hemmet during the years 1910 to 1924 inclusive there have been treated altogether 64 cases of cancer of the vulva. All these cases have been far advanced, with great local tumours and palpable glands. Probably in a considerable percentage of the cases where a lasting cure has been obtained the condition was one of septic lymphadenitis, and not of cancer metastases.

With regard to the technique of treatment, our cases may be divided into three groups. The first group comprises 8 cases, treated by Forssell in 1910-1913. The technique consisted at this time in a direct application of radium tubes to the surface of the tumour, to which the tubes were fastened by means of adhesive plasters. In none of these cases was freedom from symptoms attained. Forssell has stated in one of his papers that the cause of the bad results was largely defective technique. Owing to these unfortunate experiences we did not admit during the following three years any cases of cancer of the vulva for radiological treatment at the Radium-Hemmet.

In the year 1916 the technique of application underwent an important improvement. Use was made of dental compound mass for the application and fixation of radium preparations. This technique has been worked out at the Radium Hemmet by my colleague Dr. Berren, who during the following years has treated all cases of cancer of the vulva, to which he has devoted special attention.

During the years 1916-1922 Berren treated 30 cases. Of these, 21 were improved for a short time or remained entirely unaffected, 3 were substantially improved for about three years, and in 6 cases freedom from symptoms was obtained. In one case freedom from symptoms has lasted for seven years, in one case six years, in one case five years (the patient later died of heart disease), in one case four years, in one case three years, and one was free of symptoms for two years, when she died of heart disease. Thus freedom from symptoms for two years or more has been obtained in 20 per cent. of the cases.

However, it was found that this form of radium treatment sometimes involved severe subjective troubles, and in a number of cases severe secondary necroses. In order to avoid at least the primary reaction or the sloughing of the tumour and the issue, Berren has since about 1923

the tumour and then immediately applied radium treatment to the cleansed surface of the sore with considerably weaker doses of radium. With this technique Berren has treated altogether 26 cases, of which one has remained free from symptoms for three years, 4 for two years, and 3 for one year. More important than this primary result with regard to a lasting cure is

the palliative result that has been gained by this technique in contrast with the preceding one. In more than half of these cases, in fact, local freedom from symptoms has been obtained, and the patients have been free from their very severe local troubles until their death in consequence of metastases. In all cases the regional glands have been treated with Roentgen rays.

Method of Treatment

I have recently described in detail the method of treatment of cancer of the cervix at the Radium-Hemmet, which was worked out in principle by Forssell in 1913, and which in the main we have followed ever since (*Journal of Obstetrics and Gynaecology of the British Empire*, 1924, vol. 31, No. 1). Time allows me here only to describe its main points. We treat with radium salt and employ, as a rule, Dommer tubes.

- 1 As a rule only three applications of radium are made.
- 2 The second application is made one week after the first, and the third application three weeks after the second.
- 3 If possible, radium is applied at each of these treatments both in the vagina and in the uterus.
- 4 The duration of each application of the radium is about twenty-two hours.
- 5 A dose of 337 or 401 mg. element is used in the uterus three times, making a total dosage of about 2,220 to 2,640 mg. element hours.
- 6 A dose of 70 mg. element is used in the vagina three times, making a total dosage of about 4,500 mg. element hours.
- 7 The radium is always filtered through 3 to 4 mm. of lead.

Since 1919 a more concentrated treatment has been tried, the number of applications being reduced to two—thirty-two and twenty-four hours respectively. In such cases the total vaginal dose has been limited to 4,000 mg. radium element. All operative interference at the commencement of the treatment, such as cauterization and excoriation, we regard as absolutely contraindicated. The treatment is never repeated within the first six months.

If, six months after the three applications already mentioned, the growth has not disappeared, or if there is a recurrence, the treatment may be repeated, though we prefer not to repeat it until a year after the first treatment. Only one application is then made. Clinically cured patients, as well as patients with a suspected "reactive" inflammatory swelling, are not treated again until a recurrence has been definitely proved. If there is a local recurrence and the growth is operable, hysterectomy is performed. No difficulties in operating caused by the radiation have been noticed in these cases.

Roentgen-ray treatment we use on rare occasions only. We have abandoned the combined radium-Roentgen ray treatment, since we have found that the results were not better, but rather worse, than with radium treatment alone. Nowadays we resort to Roentgen-ray treatment in conjunction with the first series of radium treatments in those cases only in which there are extensive glandular metastases from the very beginning. It is also used if severe pain persists after the radium treatment and if there is a recurrence in the praemetrium. In our Roentgen-ray treatment we do not employ the massive doses. On each field we make two or three exposures, each of one third of an erythema skin dose, one exposure a day or every second day. The exposure is generally distributed on two anterior fields and one posterior field. We use a filter of 0.5 mm. of copper and 1 mm. of aluminium.

The above described method is our routine treatment of cases of cancer of the cervix. The variation of the dose is very limited in different cases. We try to cover if possible the whole surface of the tumour with radium, and the size of the vaginal pack is for this reason varied according to the shape and size of the surface of the tumour. In cancer of the body of the uterus the same intrauterine dose is given as in cancer of the cervix. Since cancer of the body often produces metastases in the vagina, all cases of cancer of the body are also treated with application of radium in the vagina, the dose being only two-thirds of that used in the vagina for cancer of the cervix. We have had no occasion to increase the vaginal dose in cancer of the body. The recurrences which we have observed have nearly all appeared in the body of the uterus or its surroundings. Vaginal cancer is dealt with in the same way as cancer of the cervix—that is, by intrauterine treatment if possible.

TABLE XI—Cancer of the vulva primarily treated with radium and Roentgen rays at the Radium Hemmet 1910 to 1924 inclusive

Group I—1910-1913	
Number of cases	8
Free from symptoms	0
Group II—1916-1922	
Number of cases	30
Unimproved	21
Substantially improved	3
Free from symptoms (1 for seven years 1 for six years 1 for five years 1 for four years 1 for three years 1 for two years)	6
Group III—1922-1924	
Number of cases	26
Free from symptoms (1 for three years 4 for two years, 3 for one year)	8

In ovarian cancer we give an intravenous treatment, with about 40 mg radium element for thirty hours, which is 1,200 mg radium element hours, and this is directly followed by a series of careful Roentgen-ray treatments in small doses ($3 \times 1/4 - 1/3$ S.E.D.), from a number of small fields. If the tumour does not disappear or show a tendency to decrease, the Roentgen-ray treatment is repeated at intervals of six weeks or more.

There is scarcely ever a contraindication to the radium treatment of cancer of the organs of the female pelvis. With careful dosing even a far advanced cancer in a very cachectic individual may be treated without injury to the patient.

I am not aware of any signs that enable us to form a sure prognosis. Only in cases where there is a perforation of the rectum or the bladder one might with fair certainty predict that, as a rule, not even a palliative result can be obtained.

For wellnigh twelve years we have acted mainly according to those principles which Forssell formulated in 1913. Already at that time Forssell insisted that, in order to obtain a good result with radium treatment, it is necessary, not only to damage the tumour cells, but also to maintain the normal reaction of the surrounding tissues. The careful experiments we have made in increasing the doses still further and in concentrating the treatment have not encouraged us to make any considerable changes in this respect. The results which we gained during the first years, 1914 and 1915, have not been surpassed by those gained later. On the contrary, these last results, taken as a whole, are somewhat less favourable. From this fact I am inclined to draw the conclusion that the more careful dosing which characterized the treatment during these first years is more in accord with the pronouncement of Forssell cited above, and that a further concentration of the treatment, and treatment with more massive doses, is not advisable.

Finally, the fact must be emphasized that with radium treatment, just as with surgical treatment, good results can be obtained only by a close study of the patient, a proper knowledge of the limitations of the form of treatment, a carefully planned technique, and experience. In the hands of the inexperienced the method involves great risks without any possibility of results comparable with those obtained by operation.

II—PERCIVAL P. COLE, F.R.C.S.,

Surgeon to the Cancer Hospital, London

My own contribution to this discussion will be confined to the general position and treatment of inoperable cancer of the uterus. Although primary cancer of rectum and bladder is outside the scope of this discussion, these viscera are frequently invaded. Leiten in a series of 915 post-mortem examinations found recto-vaginal fistulae in 16.5 per cent, and vesico-vaginal fistulae in 44.2 per cent of cases. Operability or otherwise of any particular case is generally decided by the extent of local invasion, for distant metastases are rare, being estimated by Leitch at less than 7 per cent.

The numerical importance of the subject before us is emphasized by the inoperability rate. In a previous estimate I placed at one end of the scale Bonney's estimate of 36 per cent inoperable, and at the other end the Cancer Hospital figure of 93 per cent estimated over a period of three years. A further and later investigation of the Cancer Hospital figures, comprising 222 cases over a period of five years, gives a slightly more favourable result at 88 per cent. I suggested then, and suggest again, that the general inoperability rate would be arrived at approximately by fusing these figures, which gives a percentage of 62. Other estimates are even higher. Thus Thomas Wilson finds 68 per cent and Fletcher Shaw 73 per cent inoperable. Heyman of Stockholm reports that the inoperability rate over a series of years, and comprising 505 cases, varied from 97.5 to 63.5 per cent, the lowest rate indicated being reached in 1921, when 115 cases were treated. Janeway assesses inoperability of cancer of the uterus as a whole—that is, including fundus cases—at 62.4 per cent.

What constitutes an operable case? That is a question difficult to answer, for published statements make it obvious that opinions vary considerably. Howard Kelly divides cases into three groups as follows:

- I With extensive lateral involvement and fixation
- II Where the lateral infiltration is moderate and where neither side is fixed
- III Where the disease appears limited to the cervix and mobility is not interfered with

In his opinion the third group only should be classed as operable. This view is supported by Clark, Janeway, and Stone. Smith¹ suggests the possible routine adoption of the Byne extirpation operation and radium at the same time, while Recasens has abandoned operation in all cases.

What are the untoward results that have combined to render the surgical attitude so conservative towards the radical abdominal hysterectomy? Janeway estimates the mortality in 1,997 cases operated on at just over 18 per cent. Bonney estimated his mortality in 1921 at 20 per cent, and although he has considerably reduced it since then it may reasonably be assumed that the general incidence is not less than this figure. Janeway estimates 35 per cent of cures of five years' standing. Bonney claims 40 per cent. The more extensive the disease, particularly if regional glands be involved, the greater is the mortality, and the less chance of cure. In this case mortality rises to 25 per cent, and five-year cures fall to the same figure. Although glandular invasion will be discussed at a later stage its incidence may be stated in passing. Weibel says that 25 per cent of all cases on which he operated had cancerous glands. Forssell estimates the incidence at 30 per cent and Leitch at 38 per cent. My own figures, previously estimated on post-mortem records, give a somewhat lower percentage of 24. Bonney found the glands invaded in from 35 to 38 per cent of his cases.

Other metastases, as already mentioned, are uncommon, and it may be estimated that approximately 60 per cent of cases of cancer of the cervix that run their course without surgical intervention die as a result of effects determined by what remains to the last a local lesion.

As an introduction to the treatment of inoperable cases by radiation the question of the use of radium to render border-line inoperable cases operable may be briefly considered. Fletcher Shaw, working with Burows, is strongly in favour of this procedure. This attitude is, to some extent, supported by Pinel, Monod and Gosset report 30 cases of hysterectomy when radium radiation preceded the operation by four to six weeks. That the operation is rendered more difficult in many cases is not denied, but the fibrosis encountered is not altogether disadvantageous, for it determines a clean operation field and makes for diminished oozing in the perivaginal and pericervical tissues. Other workers—Clark, Schmitz, and Keene, for example—are entirely opposed to this plan. They maintain that results obtained do not justify surgical intervention. Certain it is that whatever may be the surgeon's views on this particular subject, operation should not be delayed for longer than one month. Of this method I, and my colleagues at the Cancer Hospital, have no experience. Operable cases, as already noted, constitute only 12 per cent of cases admitted, and border-line cases are practically unknown. The existence of two wards set aside for the admission of chronic inoperable cases determines the constant influx of patients in whom the disease is far advanced.

I propose to treat, therefore, of the means that have been employed to deal with cases such as these, diverging from time to time to comment on the methods of other workers in the same field. The material consists of 263 cases of cancer of the uterus admitted between, and including, the years 1919 and 1925 (see Table I). A certain number of cancer cases are included in this total, but the whole series is dealt with separately later. It will be noted that 106 of these admitted cases, or 40 per cent, were untreated. This implies that examination revealed conditions—such as a large abdominal tumour, metastatic deposits, etc.—which rendered any form of treatment unavailable. The total number of cases treated by radium

¹ *Surgery, Gynecology and Obstetrics*, May, 1925.

TABLE I—Summary of Carcinoma of Cervix Cases, 1919 to 1925

Year	Total Cases	Radium	Cold Cautery	Untreated Cases					Dead	Not Traced
				Number	Had no Previous Operation	Total Length of Life	Alive			
1919	44	12	7	21	20	Months 16 25	—	20	1

Total number of cases admitted without previous radical operation 222
Number operable 27 giving an operability rate of 12.1 per cent

in some form or other is 103, or 39 per cent of the total. These cases have been treated by various members of the staff, myself included.

The radium has been made up in tubes containing 100 mg and 50 mg radium bromide enclosed in 0.3 mm platinum. This has been reinforced as occasion demanded by filters of 1 mm or 2 mm silver. There have also been at our disposal needles of varying length—12 containing 8 mg radium bromide, 2 containing 10 mg, and 6 containing 6 mg. All radium used in this way has been encased merely in 1/2 mm platinum.

Contraindications

Violent infection and cachexia would appear to be outstanding contraindications to the use of radium. Fordsike, Taussig, and Pinch stress the importance of infection, and the last named emphasizes the adverse influence of cachexia and anaemia. Briley and Healey maintain that very advanced cases are unsuitable, using, as they do, a heavy dosage. Strahan regards pyometra as a contraindication until drained. It is clear that these contraindications can be to a great extent obviated by preliminary treatment or by the use of relatively small amounts of well filtered radium. This raises the question as to whether small doses of radium are capable of exerting a stimulating effect upon the growth. Pinch on this question adopts a cautious attitude. Other observers—Fordsike, Knox, Clark, Morgan, and Asnis—are emphatic that such an untoward effect need not be feared.

No attempt has been made to differentiate cancer of the fundus or cancer of the cervix in these inoperable cases. At the Radium Institute the total incidence of cancer of the body has not exceeded 3 per cent of all the cases of uterine cancer treated, and in many instances microscopic sections show so much metaplasia of the malignant cells that it is impossible to say from which class of epithelium the growth originated.

Radium Sequelae Dosage and Method of Application

Most important of the radium sequelae is burning on the method of application are proctitis, cystitis, and fistula formation. The rectum is much more prone to inflammatory reaction than the bladder, and many measures have been adopted to protect these viscera, such, for instance, as the so-called "bomb" technique of Kelly and Bunnim. Dental composition has been advocated as a vehicle, particularly in cases characterized by a diffuse shallow ulceration. We have found that the use of needles and gauze packing obviates the necessity of employing more complicated measures. Fistula formation does occur, but only occasionally in our practice, as opposed, for instance, to that of Taussig, who, in a group of 86 cases, reports the development of recto-vaginal fistulae in 9, with concomitant vesico-vaginal fistulae in 2.

Intense local fibrosis may occur, and may, as Lewis points out, mask the incidence of malignant disease in the parametrial tissues. These untoward events are becoming much more rare since heroic doses have been abandoned, and since the importance of adopting filtration suitable to the case has been recognized. In view of the anatomical disposition of the parts involved it would appear that unfiltered glass capsules of radium emanation (Quick) are unsuited for general use. They produce an intense reaction in the tissues accompanied by a devitalizing effect, which, as Clark, Morgan, and Asnis maintain, "we in fact are learning to recognize as being what we must avoid."

General Results

The results at the Cancer Hospital (see Table II) coincide with those reported by other observers in that the local and symptomatic benefit which follows immediately is frequently most striking. This applies to the lessened degree or disappearance of ulceration, reduction in amount of parametrial infiltration, and the arrest of discharge and haemorrhage. Haemorrhage is not always checked, however, but on the contrary is sometimes caused, by radium treatment.

TABLE II—Summary of Cases Treated by Radium, 1919 to 1925

Year	No of Cases	No with Haemorrhage following Radium Treatment	No with Infection of Internal Iliac Arteries	Intra-abdominal Radium Applications	Average Length of Life after Treatment of Cases Traced and Died	Alive	Dead	Not Traced

N.B.—Each patient is only mentioned once in these tables and is entered in the year in which she was first treated; therefore there were actually more radium treatments in each year than the numbers show. The total number of radium applications was 169.

Fordsike instances 7 cases, and Taussig had 8 cases, of severe haemorrhage as a result of radium necrosis affecting a branch of the uterine artery.

Haemorrhage after radium occurred in 5 of our cases. Knowledge of this possible contingency led me to tie the iliac arteries in two or three cases in whom, before admission, violent haemorrhage had occurred. Radium insertion via the vagina was carried out at the same time. With my hand in the abdomen I was able to check the movements and manipulations of my assistant who was inserting the radium. The uterine sound presumed to have passed through the cervix into the uterine cavity presented under the peritoneum of the utero-vesical pouch, and the points of two needles supposed to be embedded in growth perforated the peritoneum on the postero-lateral aspect of the cervix. Whatever may be the merit of internal ligature in association with radium application, the advantage of opening the abdomen cannot be denied, in that the disposition of the radium can be accurately determined. The method has been employed only in the worst type of case—the type in which deep ulceration and infection has seemed to render consequent haemorrhage a likely happening and in which anatomical landmarks have disappeared. Twelve cases have been dealt with in this way. One died ten days after the operation, and at necropsy no definite cause was found. Three are alive—one, after twelve months, quite well and with no sign of growth; two after ten months, one with and the other without signs of recurrence. The average duration of life after operation of those dead is 12.5 months. Two of these deserve brief further mention.

Mrs H.E. aged 40 was admitted on April 6th 1923 with advanced carcinoma of the cervix. There had been constant haemorrhage on the voyage from Aden. Her condition was deplorable—anaemic, cachectic and with offensive blood stained vaginal

discharge. The cervix was extensively destroyed and bladder and rectum were infiltrated. On April 13th portions of the growth were scraped away and the vagina packed with gauze soaked in acetone. On April 28th the internal iliac arteries, ovarian arteries, and round ligaments were ligated, 50 mg radium with 2 mm silver filter were placed in the cervical canal for twenty-four hours. Radium treatment was carried out at intervals of two to three months on five occasions but after the fifth application she complained of pain in the back and thighs. A year after her first admission she developed cerebral symptoms and died. *Post mortem* examination was not allowed and the suggested cause of death was cerebral thrombosis. Locally there was no sign of growth.

Improvement in the local and general condition of this patient was astounding, but the outstanding feature was the suppression of pain which resisted all endeavours to allay it. This is a possible, and most distressing consequence of multiple applications of radium. It would, perhaps, have been better had the patient been left alone after the second, or at any rate after the third, application.

Mrs A. W., aged 49, was admitted on May 24th 1924. Violent haemorrhage having occurred three weeks previously the vagina had been packed at the Royal Free Hospital. The patient was very anæmic and weak. The cervix was small, hard and fixed to the surrounding tissues. On June 13th the internal iliac arteries, ovarian vessels and round ligaments were ligated. Six radium needles (48 mg) were inserted for twenty-four hours. Two other radium applications followed.

In April of this year the patient was in good health clinically there was no evidence of growth.

Besides simplifying the disposition of radium introduced by the vagina, opening the abdomen has the advantage of allowing the insertion of radium into growth which otherwise would be inaccessible. The treatment of pelvic extensions and glandular invasion is a matter that has attracted considerable attention. Ingenious methods have been devised for the application of radium in such positions. Chief among these is the "cross fire extraperitoneal pelvic irradiation method" described by Driels and de Backer. These authors have been induced to elaborate their extraperitoneal technique in this "now it may be looked upon as a classical rule that radium puncture of cancerous glands ought to be condemned and that external 'Curie' therapy is to be preferred by a long way to Roentgen therapy for the treatment of these cancerous glands." Of this method neither my colleagues nor I have any experience. Donaldson employed it in 14 cases, but objects to it on various grounds. I suggest that it is far too blind a method to appeal to the modern surgeon. The intraperitoneal insertion of radium needles has been employed in a few cases, but present data do not permit of the formulation of any definite conclusions.

Systematic radiation of the pelvis by x-rays after local radium application by the vagina has been attended by encouraging results. This sequence has been commented on recently by Lynham. The method adopted has been interrupted dosage by multiple points of entry. Brief notes are appended of three outstanding cases.

Mrs J. P., aged 54. On admission (October 3rd 1922) the patient was thin and worn. The whole anterior aspect of the cervix was occupied by an epitheliomatous growth, the left broad ligament was invaded and was adherent to the pelvic wall, the right broad and utero-sacral ligaments were also involved. On October 11th a radium tube containing 100 mg with 1 mm silver filter, and 5 radium needles (each 8 mg) were inserted for twenty-four hours. On December 2nd 50 mg radium with 1 mm silver filter and 4 needles (each 8 mg) were inserted for twenty-four hours. X-ray treatment was given in November and December 1922, in January and March 1923 and in January 1924. On June 2nd 1925 the patient was clinically free from growth. Palpation suggests that panhysterectomy has been performed.

Mrs J. C., aged 54, was admitted on May 22nd 1923. Panhysterectomy had been performed at Leeds in February 1922. Recurrence was noticed in December 1922. On admission there was recurrence in the vaginal vault with secondary deposit in the liver. On June 11th 1923 radium 100 mg and 1 mm silver filter were inserted for twenty-four hours. X-ray treatment was given in December, 1923, in July and November 1924 and in April, 1925. At the last date the patient was well. The mass in the liver had practically disappeared. Locally there was no evidence of growth.

Mrs A. J., aged 54, was admitted on June 12th 1923. In March, 1922, she had undergone panhysterectomy at the Royal Free Hospital. In February 1923 there was recurrence in the vaginal vault. On June 13th 1923, radium 50 mg and 2 mm silver filter were inserted for thirty-six hours. On June 14th 1924 she had slight discharge and occasional haemorrhage, a small nodule

filter were inserted for sixteen hours. X-ray treatment was given was seen in the vaginal vault. Radium 50 mg and 2 mm silver in May, June, September and November 1923, in April, 1924 and in March and April, 1925. In May 1925, she was alive and well and clinically there were no signs of growth.

Recessens also supplements radium by x-ray treatment. He also comments favourably on the combination with this treatment of intravenous injections of colloidal metals—copper, platinum, and electro-selenium. He states that in all cases in which radium was employed after treatment with colloidal copper the symptoms of cervical cancer disappeared more rapidly than when radium alone was used. We have tried these colloidal preparations, but have nothing favourable to report in this class of case.

Our experience of recurrence is in accord with that of Finch, who finds that these do better than primary inoperable cases.

Of 18 cases dealt with in this series 4 have been untraced and 8 have died with an average length of life after radium treatment of 10.5 months. Six are alive, one fourteen months after, labelled "fairly well", the other five are well and free from subjective and objective signs of growth at intervals of four years, two years, five months, two years, two years, and five months. In four cases carcinoma has originated in the residual cervix after a supravaginal hysterectomy for fibroids. Two lived six and sixteen months respectively. The other two are alive and well six months and one year after treatment.

It will be seen that the average length of life in those who died after radium treatment has been little greater than might reasonably be expected in untreated cases. Results are, however, undoubtedly improving. As opposed to those who have died, 17 cases are living and clinically free from growth at various intervals after operation (see Table III), and fifteen others are still living at various intervals up to fifty-nine months, but in these obvious signs of growth are present.

Dosage and periodicity have varied, the largest used being 210 mg for twenty-four hours, and 200 mg for forty-eight hours. In the latter case the patient died from haemorrhage seven months later. A brief summary of the dosage used and time exposure in successful cases indicates that the number of treatments varies from a single dose up to multiple doses at intervals of three to six months. The dosage employed has been, comparatively speaking, small, the tendency being to determine an increased milligram hour exposure by lengthening the time and not by increasing the amount of radium. No untoward results have attended the use of needles. On the contrary, they have proved an efficient and convenient vehicle.

Results Compared with those of other Workers

Comparison in this matter is difficult, for investigation clearly shows that the greater the number of relatively early cases that are included the better are the results obtained. Existing figures, based on the treatment of a large number of cases, are published by Chail, Bailey and Healer, Schmitz, and Taylor. Further figures will be found in the recent papers of Donaldson and Strachan.

Fifteen cases are still living but with obvious signs of growth.

These figures culminate in the truly amazing figures submitted by Heyman of Stockholm, who admittedly includes in his radium-treated cases many which would be considered operable. Thirty-six cases were treated in the years 1914 to 1918, and of these 14 are symptom free, or

clinically cured after five years. This gives a percentage of 40.5, and compares favourably with the best figures submitted as a result of the major abdominal hysterectomy.

Certain outstanding effects are noticed in the reaction associated with the radiation of carcinomatous tissues.

- (1) That various degrees of degeneration and destruction may be determined, the effect produced being dependent upon dosage and filtration.
- (2) That cells vary in radio-sensibility.
- (3) That various histological changes in the invading cancer cells and in the invaded tissue occur according to the dosage and the time elapsing after radiation.
- (4) That cancer cells are more vulnerable when in a state of active division.

These phenomena are of vital importance in the consideration of the changes that have occurred in the conception of radiotherapy since its introduction and have a pertinent bearing on the question of dosage. The transition in the conception of radium treatment since its inception is ably summarized by Lazarus Birlow. In the beginning regarded as a species of specialized caustic, through the stage of endeavouring to determine a directly selective destruction of cancer cells, there has, last of all, arrived in the minds of some authorities the conception of irradiations as an agent whereby the resistant factor of the normal tissues is stimulated and reinforced—in other words, the envisagement of a biological factor.

The radiological department of the Cancer Hospital, under the charge of Dr Robert Knox, has always been opposed to the conception of the "lethal dose" of Seitz and Wintz, and to the view of these authors that the destruction of cancer cells is a physico-technical task, and that the biological incidents are confined to the removal of the destroyed cancer epithelia.

Tumour growth occurs in cycles, and, because cancer cells in active division are more vulnerable, Knox maintains that interrupted dosage, or well filtered dosage over long periods, has definite claims to consideration. Other prominent exponents of the biological, as opposed to the purely physico-technical, view are Living, Pinch, Opitz, and Colwell and Russ. Histological studies bearing upon the present discussion have been published by numerous investigators, among whom may be mentioned Alter, Colwell and Puse, Donaldson and Cunti, Kehrer and Lahn, Martzloff, Pinch, and Schmitz. Particular stress is laid by Donaldson and Cunti on histological examination of tissue removed from irradiated cases of cancer of the cervix. They make the interesting observation that degenerative changes in the cancer cells precede fibrosis, and confirm similar observations made by Foidsike at an earlier date. It follows that fibrosis cannot be the cause of growth regression in irradiated tissues, and it is possible that in the so-called "natural" cure of cancer the same sequence obtains. Fibrosis follows cancer cell degeneration but does not determine it.

It is to be regretted that histological data in the present series of cases are so incomplete as to be practically useless. Histological facts, unless accurately coordinated with clinical manifestation of success as determined by freedom from growth and length of life, will not, however, help to solve the problem. For just as we have no idea how or why changes arise in tissues subjected to radiation, so also we have no idea as to the particular histological changes associated with the greatest material and lasting benefit to the patient. In the case of the hardest gamma rays it is not even definitely decided whether growth recession is due to a direct action on the cancer cell. Thus Colwell and Russ state:

That a destruction of the malignant cells occurs as a result of the irradiation is no doubt true in some cases, but Dominici submits considerable evidence to show that this is by no means always the case or indeed necessary for the ultimate resolution of such cells.

The radical change in views as to mode and cause of action in the case of radium is clearly indicated by reference to excerpts from modern writers on the subject.

Opitz emphasizes the biological view in a recent paper and delivers himself as follows:

"If the view here set forth of the effect of the rays is correct then the specific effects observed in the case of galvanization, light treatment, heat action, diathermy, etc. must be brought into relation with those of Roentgen and radium radiation."

Is it not possible that our views as to the effect of heat will have to undergo similar changes to those which have obtained in the case of radium and x-rays? The long-wave radiation, usually called "radiant heat," is essentially a radiation the energy of which becomes transformed into heat by absorption in passing through solid or liquid.

The exact biological action of varying degrees of heat upon the tissues is no more understood than the action of the gamma and x-rays. There is some evidence, however, to show that the tissue reaction in the two cases is somewhat similar. In 1920 W. J. Mayo, in an article on "Cancer and the prolongation of human life," stated that "Radioactive substances give great promise for the future. I would include with radium and the x-rays the radiant energy of heat." Ishii and Loeb, studying the effects of heat upon the growth of mouse carcinoma, found that the longer the exposure to heat (44°C) the less interaction between connective tissue and tumour, the more dense fibrous tissue is found (longest heat exposure thirty-five minutes *in vitro*). They conclude, among other findings—

"that in the heated pieces especially those heated 30-35 minutes, the tumour growth is retarded. Within the first week after transplantation and as a result of this inhibition the connective tissue has an opportunity to form a fibrous capsule surrounding the necrotic material and including much of the living tumour material. This formation of a fibrous capsule is a second effect, inhibiting the growth of the heated tumour. It represents a mechanical impediment to the tumour growth and it diminishes the nourishment carried to the tumour tissue through the blood vessels."

Loeb, studying the effect of Roentgen rays and radioactive substances on living cells, finds that the effect of radiation on tumours is in many respects similar to the effect of heat on tumours. It may be urged that such findings cannot be regarded as convincing, in that they apply to conditions not comparable with those that obtain in human malignant disease. They are, at any rate, suggestive, and their suggestiveness is emphasized by the fact that cases successfully dealt with by the application of heat present the same clinical features as successful cases treated by radiation. In both cases there is slow regression of tumour growth, absorption of surrounding infiltration, and steady increase in plasticity and mobility, until the final condition is comparable in typical cases with that which obtains after hysterectomy. The use of heat in the treatment of carcinoma of the cervix particularly, was practised and urged by Byrne in the eighties of last century. At the time of his death he is alleged to have had 400 cases to his credit, without an operation death, and with a permanent recovery rate of 19 per cent. Byrne dealt with the earliest cases by cautery excision.

Since then many changes have occurred in the adaptation and mode of employment of heat. For many years it was employed as Byrne employed it, to produce local destruction. This was followed by the long exposure to low-grade heat advocated and practised by Percy. What is the nature of the connective tissue response, or how it is produced, is not known, but the existence of such a factor seems to be the only way to account for the amazing results that have at times followed this type of treatment in apparently hopeless cases. The biological factor is one that may reasonably be postulated in the case of the long-wave radiations of heat as in the short-wave radiations of x-rays and radium. The cautious operation of Percy has not found favour in this country, but it has been more or less freely employed in America, and the results obtained have determined divergent views as to its utility.

Schmitz, Taylor, and Bailey and Quimby, in discussing the merits of cauterization either by the orthodox Percy method or by some modification thereof, are of opinion that the results obtained do not justify the use of such

methods, particularly in view of the added physical and material sacrifices. A consideration of their criticisms further indicates that their arguments are un- soundly grounded. The technique employed has often been at fault and the post-operative use of radium described by Bailey and Quimby is such as would not be countenanced by any modern surgeon conversant with its effects.

As against these unfavourable opinions may be cited one of an important and commendatory nature. In a discussion on Skell's paper read at the thirty-fourth annual meeting of the American Association of Obstetrics, Gynecology, and Abdominal Surgery, Dr. Ambel Brown quoted a letter from W. Mayo, stating that results from the Percy cautery operation had been entirely satisfactory in the Mayo Clinic, but as it was no more cumbersome than radium the latter was now more often employed because of its convenience.

In previous papers reference has been made to the literature of the Percy operation, together with a description of the technique now adopted. The total number dealt with to date is 61. The results are indicated in Table IV. The

Three cases were not traced: seven are alive and well at periods after operation of 7 years 11 months, 7 years 3 months, 20 months, 16 months, 6 months, 4 months, and 4 months.

Average life duration of those who have died has been 13.9 months after operation, which compares with 8.9 months in the radium cases after treatment, and a total duration of life of 14.8 months in untreated inoperable cases. The primary mortality—that is, cases dying within one month of the operation—has been 10 per cent., and these cases have been included in assessing the average duration of life. Viscero-vaginal fistula occurred as a direct result of the operation in 7 cases in the first series of 43. In the following 18 cases it has only occurred once. The advantages of opening the abdomen in these cases are manifold. In many cases it has been clearly demonstrated that any considerable prolongation of life cannot be expected, the main object being alleviation of distressing, and frequently disgusting, symptoms. Dilated ureters on one or both sides, adherent inflamed tubes, in some cases suppurating, adhesion of omentum, or small or large bowel, to the pelvic viscera matted together by growth or inflammation, the existence of dense indurated tissue spreading along the sheaths of the large vessels, and finally, the presence in a few cases of large masses of malignant glands, have complicated the intrapelvic condition.

At times the ligation of the internal iliac arteries has been very difficult, occasionally it has been impossible. Pionetria has been present in the majority of cases. The statements previously made as to post-operative progress and absence of shock hold good in respect of the added cases. Radium is inserted by the vagina some six to eight weeks after operation, provided local conditions seem to demand or warrant its use. In any case the amount employed is small, and needles are almost invariably used. The relief of symptoms is striking, a phenomenon seen in the radium cases. Douching is resorted to soon after operation to get rid of the discharge, which is very thick, and to prevent fusion of the vaginal walls by a process of adhesive vaginitis. A more detailed account of two of the patients who died will indicate the scope of benefit in very advanced cases.

Mrs. M. G. aged 46 was admitted in January 1920 with advanced carcinoma of the cervix with secondary mass at the vaginal inlet. Cautery operation in January was followed at a later date by excision of the secondary mass with knife and diathermy. This patient led a normal active life free from all symptoms until five months before her death. She developed intestinal obstruction was short-circuited but died in February, 1925 five years and one month after the first operation.

Mrs. E. S. aged 58 was admitted in September 1921 with profuse vaginal discharge and intermittent haemorrhages. The patient was a refined well educated woman and was very sensitive as to her condition. A growth of the intra-canalicular type invaded the anterior and posterior vaginal walls. At cautery operation a large mass of glands was found on the right side extending to the bifurcation of the aorta and the right internal iliac artery could not be tied. In March 1922 50 mg. radium and 2 mm. silver filter were inserted into a small aperture in the vaginal vault. It was then noted that discharge had entirely ceased and that the condition was almost incredibly improved. This patient led a normal active life until a week or so before her death which was due to uraemia and occurred fourteen months after her operation.

As representative of living cases I append two short histories.

Mrs. Maud D. aged 32 had been examined in the gynaecological department of the Bedford General Hospital and St. Bartholomew's Hospital. She was admitted to the Cancer Hospital on the score that nothing further of value could be done for her. Cold cautery operation was performed and since her discharge she has led a vigorous and useful life. Indeed she has been the main bread winner for the family for her husband has been unable to work and she has two small children. She came for examination on June 4th of this year and her sole complaint was headache recurrent attacks of which have worried her for years. Otherwise she was in perfect health with no evidence of growth and no symptoms bespeaking it. In other words she is alive and perfectly well seven years and three months after her operation.

Mrs. Eliza B. aged 57 was admitted on September 22nd 1923. The cervix was occupied by an excavated ulcerating mass the base was ragged and hard there was infiltration of the mucous membrane and hard nodules about the size of a pea in the anterior and posterior vaginal fornices which had involved the overlying mucous membrane. On October 5th cold cautery operation was performed. No glands enlarged were seen but there was a mass of growth lying lateral to the cervix in each broad ligament. On November 19th two radium needles (16 mg.) were inserted for twenty-four hours. The vagina and fornices were clean and healed the external os admitted a finger tip. Since discharge this patient has lived a perfectly normal life. She has stayed with relatives in France for some months and reported at the Cancer Hospital at the end of May. There was nothing to indicate the presence of growth and the condition of the vaginal vault and fornices suggested that a hysterectomy might have been done. She is perfectly well twenty months after her operation.

Considering results as a whole it will be noted that the number of cases which are not benefited to any material extent is large. This might well be expected in view of the type of case dealt with, and it is perhaps questionable whether more conservative selection should not be exercised. Certainly if the end in view were the compilation of favourable statistics a large number of the cases in the present series would have been rejected. The patient's point of view has been the main consideration, based on the very germane knowledge that results cannot be assessed or predicted in terms of the local condition. Comparable conditions, apparently hopeless, will, in one patient, be followed by early death and vindication of all that pessimism could apprehend, in another a veritable resurrection occurs, it may be for only two or three years, but at any rate the benefit obtained has made it worth while. Is there no means of determining the probable result in cases similarly situated—any method of prognosis that can help in the selection of favourable cases to the elimination, for the patient, of useless interference and to the conservation of energy for ourselves? There is certainly a chemical classification which roughly grades cases in order of malignancy and is of some value, as far as radium goes, in determining dosage and filtration. The proliferative fungating type is regarded as of least malignancy, and the endocervical medullary excavating type is most malignant, while the flattened ulcerative type occupies a position between the two. In some ways this classification subserves a useful purpose, but it certainly does not suffice to tell us what we want to know.

From the histological standpoint it has been demonstrated that the differentiated squamous-cell carcinoma, the adenocarcinoma, and the basal-cell carcinoma, exhibit

resistance to the direct action of radium in the order named. The possible classification of the squamous cell types has been the subject of an interesting investigation by Martzloff.

His conclusions are based on data relating to 387 cases having complete clinical and histological records. He distinguishes three types of epidermoid cancer of the cervix: (1) Spinal cell type, found in 15.5 per cent of cases; (2) Transitional cell type, found in 66.8 per cent of cases; (3) Fat spindle cell type, called by many observers "basal cell," found in 12 per cent of cases. The clinical history of each case reported on was noted and correlated with the histological nature of the growth. Of 290 cases operated on, 38.8 per cent belonged to the spinal type, 15.1 per cent to the transitional, 4.76 per cent to the fat spindle, and 21.4 to the adenocarcinoma. Of traced five-year cures the spinal type claimed 47 per cent, the transitional 24.2 per cent, and the fat spindle 9.5 per cent.

These results confirm the author in the view that "the findings are strongly indicative that the histological character of the predominant type of cancer cells in cervical epidermoid cancer is a good indication as to the relative malignancy of the neoplastic process." Attention is called to the similarity of the conclusions arrived at to those promulgated by Broders in the case of epithelioma of the lip. This observer, from statistical data compiled from a series of 537 cases, concluded that clinical malignancy and gland invasion was in inverse ratio to cell differentiation. Thus his Grade I (least malignant) group, in which the epithelial cells showed the greatest differentiation, corresponds to the spinal cell type of Martzloff. In the cervix, whether the malignancy in a particular case is constantly related to the histological nature of the growth is surely to be doubted, but it is at least suggestive that the best results from radium are obtained in the case of so-called basal cell cancers, not because they are less malignant apparently, but because they are more susceptible to its action. On the other hand, the highly differentiated epithelial type is, as previously noted, very resistant, and may demand for its eradication with radium a dosage and filtration which may devitalize normal tissues and so interfere with their reaction as to render abortive a well meant but ill calculated attempt to cure.

It may be that in this type cauterizing methods will subserve their most useful purpose. In the treatment of pelvic extensions and invaded glands coeliotomy as a means of direct attack would appear to merit a wider application, and it is along this line, I suggest, that endeavour should be concentrated with a fair promise of gratifying success. Alternatively attention should be directed to determining the best method of pelvic irradiation to be used in conjunction with local measures. The results and experience at the Cancer Hospital of radiations generally in the treatment of inoperable cancer of the uterus do not warrant us in adapting them to operable cases.

William S. Stone, Clinical Director of the Memorial Hospital, New York, maintains that—

"in uterine cancer radium has achieved its most brilliant success as a curative agent, especially in cancer of the cervix, in which surgery has now a very limited field if any of applicability."

We cannot endorse this dictum, but rather echo the words of Clark and Keene, who say

"as matters now stand irradiation has unquestionably won its right to a place along with surgical means for it has stepped into the inoperable breach with hopeful assurance of a large alleviation of suffering and a minimum probability of cure."

I wish to express my very hearty thanks to my colleagues for permission to use their cases and records to the Statistical Department of the Cancer Hospital and to Miss Geraldine Barry my house surgeon for able and welcome co-operation.

III—MALCOLM DONALDSON, M.B., B.CH. CAMBR.,
F.R.C.S.,

Assistant Physician Accoucheur, St Bartholomew's Hospital,
Obstetric Physician, Royal Northern Hospital

UNTIL recent years attention, quite rightly, has been concentrated on the treatment of early cases of malignant disease, and the position of the inoperable patient has been considered so hopeless that no real attempt has been made to deal with it. Lately, however, with the greater knowledge of radiological treatment, hope has once more been revived. It is of some interest and importance to notice how the general opinion of the profession on the radiological method of treatment has undergone changes. When it was first discovered that malignant tumours rapidly diminished in size or even disappeared under the influence of irradiation, either from x-rays or radium, the cry went up that the cure of cancer had been found. Following this, many people who had no knowledge whatever of the treatment hired radium or bought an x-ray set, and found to their dismay that they did not get the expected results. This caused a wave of depression and scepticism, which is now only just beginning to subside. In my opinion, the right attitude to adopt is neither optimism nor pessimism, but merely to hang on to the fundamental fact that malignant growths do disappear under irradiation. That fact in itself is sufficient reason to make it imperative for the whole profession to combine in working out to the utmost this line of treatment. It is at present the one and only real hope we have for the solution of this problem.

I propose to discuss the treatment of inoperable cancer of the pelvic organs under the following headings:

- 1 Statistics
- 2 Early diagnosis
- 3 Treatment of inoperable cancer of the cervix
- 4 Treatment of inoperable cancer of the body of the uterus
- 5 Treatment of inoperable cancer of the vulva
- 6 Treatment of inoperable cancer of the ovaries
- 7 Organization of further facilities for research
- 8 Possible organization of treatment centres

Statistics

If we look at the statistics for 1922 we find that the total number of deaths registered in England and Wales was 466,780, and of this number no fewer than 46,903 died of cancer, that is to say, rather less than one-tenth of the deaths were due to this dreadful scourge. Of this 46,000, 5,354 were due to malignant disease of the female genital

organs. I have not the least doubt in my own mind that the figures are even worse than here indicated, because some people only put the terminal events on the death certificate and leave out the main contributory cause. Even so, the figures are terrible, especially when one considers that so many of these patients are only middle aged.

Early Diagnosis

Although the importance of early diagnosis of the disease is well known to everybody, yet I feel that it is essential to dwell for a moment on this aspect of the problem, and in the discussion to follow I would like members of this Section, especially those of you who are in general practice, to suggest methods by which the present dreadful state of affairs can be remedied. All gynaecologists must be struck by the fact that the patients in the majority of cases only come to them when the disease is very far advanced. The reason for this I have often tried to discover, and unhesitatingly apportion the blame, first, to the public itself, and secondly, in a minor degree, to past generations of medical practitioners, but certainly not to the present-day practitioners, as in the vast majority of cases you will find that the patients in question only consulted their doctor for the first time a few days before they were referred to the hospital. I have not a shadow of doubt that the reason why, in a number of cases, they postpone seeking advice is that they fear lest they should be told that they are suffering from malignant disease and that a big operation is necessary. In the case of inoperable carcinoma of the uterus there is yet another reason—namely, that the first symptom is menorrhage. This symptom is so common among women and so difficult for them to distinguish from a slight irregularity of their menstrual period that they come to regard it as insignificant. This is particularly true of women passing through the menopause, and when one patient is told, quite rightly, after careful examination, including diagnostic curettage, that she need not worry about haemorrhage, her neighbours who appear to be suffering from the same symptom diagnose their own cases as being identical. Another fallacy that the public still cling to is that cancer is never present without pain, because by the time they realize that their relative is dying of cancer the patient in question is suffering agonies.

You may be surprised that I should apportion the blame to past generations of doctors, but it must be remembered that years ago the successful treatment of even early cases of malignant disease was so problematical that I am convinced that medical men did not try to diagnose cancer, but preferred to keep the patient and themselves in the dark. How, then, are we to remedy these defects?

First by educating the public and getting them to talk about cancer. If one advocates this, the objection is sometimes raised that it will create a panic and increase the number of cancer phobias. I entirely disagree with this idea. On the contrary, it is likely to diminish these cases. An apt comparison is the case of tuberculosis. Many years ago the dread of consumption, as all tuberculosis was called, was very great in the minds of the public. It is true that the percentage of arrested cases improved enormously, nevertheless, if we look at statistics for 1922 we find that the actual number of people in England and Wales who died of tuberculosis of all sorts is greater than the number who died of cancer, and yet the number of cases of tuberculosis phobia is comparatively insignificant because the public are sufficiently educated to realize that they are not suffering from the disease. If we can persuade the public to visit their doctors and openly say to them, "I have come because I want to know whether I am showing any signs of cancer," the problem would be more than half solved. In these days there are comparatively few medical men who are not well grounded in the early diagnosis of cancer, but it cannot be expected that a busy practitioner can go completely over a patient who comes to him complaining of some slight mythical ache or pain in the chest or abdomen, when what she really wants him to do is to see whether she has got cancer of the uterus. That is no exaggeration, it has happened

to me times without number, but being a gynaecologist I know from the outset that they have not come about the pain complained of in their big toe.

Treatment of Inoperable Cancer of the Cervix

Of all types of inoperable cancer of the pelvic organs carcinoma of the cervix is by far the most common. It is a subject to which I have given a good deal of attention in the last four years, and I should therefore like to speak rather more fully on this type of growth than any of the others. Although very malignant, in the sense that in the majority of cases it is of rapid growth, yet metastases outside the true pelvis are not very common, even in cases dying of the disease, death being more often due to general infection, toxic poisoning, and general cachexia, all of which are greatly aggravated by the frequent haemorrhages. In addition to the fact that the disease remains local for a considerable time, the effects of treatment are readily ascertained, because a large proportion is visible in the vagina, and sections can be taken before and after treatment without harm to the patient, and even without her knowledge. The above considerations show that carcinoma of the cervix is extremely suitable for treatment under research conditions.

Description of Technique.—Naturally, during these years of research, we at St Bartholomew's have modified the technique from time to time, but we have kept to the one general principle of burying the radium in and around the growth. There are authorities who criticize this principle, on the grounds, first, that burying the needles may produce sepsis under conditions very suitable for the growth of organisms, secondly, that the injured normal tissues may be affected by the radium to an undue extent, as it is well known that radium affects cells which are about to go into mitosis, and thirdly, that any incision, even the introduction of needles, may disseminate the growth. On the other hand, the drawback of superficial applications is the very localized effect of radium, the irradiations from which obey the inverse square law. The following concrete example will make this more clear. If a tube made of 0.5 mm platinum and containing 100 mg radium element be placed in the cervical canal for twenty-four hours there is a very definite effect on the immediately surrounding tissues. However, histological examination of the glands 5 cm away will show them to be entirely unaffected by the radium. This is not surprising, as in view of the above-mentioned law it would be necessary to keep the tube in position for twenty-eight years if the glands are to receive the same amount of energy as that received by the tissues adjacent to the tube in the first twenty-four hours.

Vaginal Treatment by Superficial Application.—As stated above, some authorities only place the radium in the cervix and in the vagina on the surface of the growth, and with these people the usual routine is as follows:

The vagina is prepared by means of douches but the growth is not cauterized or in any way interfered with. One or more tubes are placed in the cervical canal containing in all approximately 50 mg of radium element with a filter of 0.5 mm of platinum. In the vagina there are more tubes heavily filtered with 0.5 or 1 mm of platinum and sometimes these have additional filters of cork or aluminium and rubber to stop the secondary rays coming from the platinum filters and to act as distractors. The amount of radium contained in these vaginal tubes is 25 to 30 mg of radium element, making 75 to 80 mg in all. The exact details of the filters vary in different clinics. The duration of application also is a matter of opinion, some authorities advocating twenty-four hours, others as much as a week or even more. On the whole the tendency seems to be to lengthen the duration of exposure.

Vaginal Treatment by Burying Radium Needles.—At St Bartholomew's Hospital we are adopting at the present time the following technique:

The patient is douched for two or three days before the operation with weak lysol. At the time of operation she is placed under an anaesthetic in the lithotomy position and the vulva and vagina cleaned with pierce acid 3 per cent in spirit. A microscopic section of the growth is then taken in every case in which the radium is applied for the first time. The needles are placed in and around the growth, keeping as far as possible about half a centimetre of tissue between each needle. The longer needles are pushed outwards as well as upwards into the base of the broad ligaments. The whole vagina is then packed with gauze soaked in firmine

(2) The striking difference is that the ulcer takes very much longer to close down and heal—twelve to fourteen weeks, in contrast with the six weeks of the divided dose.

It may become callous and never completely heal, the walls being composed of hard fibrous tissue which is incompletely covered with epithelium, and in this condition there remains a thin irritating discharge, when the ulcer gets into this condition further exposures to radium are dangerous and a burn is quickly produced followed by a secondary haemorrhage. Twenty per cent of these patients complained subsequently of rectal or vesical tenesmus which required treatment for some time, although precisely the same cure was taken in packing the vagina. In the divided dose I never had a patient complain of rectal trouble, and only transient symptoms of the bladder. I have consequently retained to the method of the divided dose, provided the patient can be induced to have an anaesthetic on three occasions. The remote results I hope to record in due time.

Type of Case

For convenience the cases should be divided into three classes: (1) Early cases—those clinically limited to the cervix, (2) border-line cases—those which clinically exceed the limit of the cervix, involving the parametria, vaginal walls, or utero sacral ligaments, and in which the uterus is tethered but not fixed, (3) advanced cases, which are admitted to be beyond the aid of surgery. The early cases do not come within this discussion.

Border-line Cases

It is admittedly difficult and sometimes impossible to determine whether the outlying induration is due to growth or inflammatory oedema, but rest in bed, disinfection of the cervix, and drainage of the vagina will frequently dispel the doubt and either confirm the classification or restore it to the early class. The morbid histology of these cases must be investigated to clarify our ideas of operability, it is recognized that the microscopic edge of the tumour lies well beyond the clinical edge and can frequently be demonstrated on microscopic section 1 to $1\frac{1}{2}$ and even 2 inches beyond.

It is instructive not only to examine the organ removed with the naked eye, but to take microscopic sections from various parts of the periphery of the cervix, in more than half the cases the knife will be found to have passed through the microscopic tumour. Furthermore, a snip of tissue should be taken from the pelvic side of the wound, and again in more than half the cases healthy cancer cells will be found on microscopic section. I investigate my cases in this way, and I recommend all surgeons to do the same thing, for it will enable them to estimate how soon recurrence will manifest itself clinically. Of my 20 Wertheim cases after radium 11 showed that division had taken place through the microscopic tumour, although to the naked eye it was well beyond the growth. There was this comfort, however, the cancer cells were not healthy, but showed all the degenerative changes of malignant cells which had been exposed to radium, changes which I have described fully in my Jacksonian essay. The changes noted in the cells are followed by an enormous increase in fibrous tissue which eventually surrounds them, and the malignant cells are strangled and disappear.

In my Hunterian Lecture last year I recorded the results of 50 border-line cases which survived the Wertheim operation, of that series three only are alive to day, six, five, and four and a half years after the respective operations, 29 (58 per cent) occurred within a year, 9 (18 per cent) recurred between one and two years, 9 (18 per cent) survived for varying periods of time up to three and a half years.

Martozloff (Johns Hopkins Hospital) reported that of 120 border-line patients submitted to the Wertheim operation less than 10 per cent were alive at the end of a year, and that the mortality rate varied between 25 and 70 per cent, depending upon the extent of the growth.

Operation in this class of case results in a high mortality, a number of abandoned operations, many incomplete operations, and a few cases which remain well over a variable period of time. It is time that we faced the situation

frankly, and realized that the Wertheim operation is over-extended. I have no doubt that these cases should be treated by radium, as a result of which a certain number will become operable, a certain number cured, and the remainder will survive for varying periods of time—one to five years—in a condition of comfort and ease and able to pursue their home duties to within a few weeks of the end.

In arguing that border-line cases should be treated by radium, I am too well aware of a real difficulty. What about secondary deposits in the pelvic glands? Is radium going to deal with them? We know that 30 per cent have glandular deposits, and unless we can offer some rational mode of dealing with them we are simply transferring that 30 per cent to the third group and treating them palliatively.

I think we may dismiss the methods of Driels and Donaldson without much consideration, for the former is a blind operation of uncertainty, and the latter's plan of packing the pelvis with gauze for several days is fraught with danger.

The direct plan of opening the abdomen and implanting the radium in the growth, which I have now tried three times, has strict limitations and cannot be carried to a conclusion. There remains but one method, and that is the combination of x rays for the pelvic deposits with radium for the local lesion. This method has now been tried for a considerable time by Kelly, Doderlein, Reensens, and Zweifel, and they give a good account of the results. Reensens treats all cases of cancer of the cervix by radium and x rays, and claims 25 per cent five-year cures from it. It is difficult to assess the value of this result without knowing more detail of the cases. Zweifel (Munich), using the same method, claims 43 per cent of cures in operable cases, and 7 per cent of cures in inoperable cases. It would be desirable to have the reports from a larger number of clinics, where the cases were divided into three classes: (1) early, (2) border line, (3) late.

Advanced Cases

These cases, which all agree are inoperable, form a large majority of those sent for treatment. What are the results in these cases? Ninety per cent of them are eligible for treatment, the remainder being debaired owing to one of the conditions referred to under contraindications. Those who are not beyond the aid of radium receive a very large measure of benefit: in 85 per cent haemorrhage ceases, the discharge loses its offensive character, becomes thin, and disappears entirely with the healing of the local lesion in four to six weeks, pain is frequently relieved, and the general condition is so much improved that the patient is able to resume charge of her home, and continues to do so until a week or two of the end. A few of these cases are cured clinically and remain well over periods of two, three, and four years, life is prolonged for a majority of them from six to eighteen months, and all of them enjoy a degree of comfort which no other form of treatment offers them.

The surgeon who treats these cases with radium, seeing so many of them, is apt to be discouraged by the end results and forgets the benefits conferred by it. Little or no improvement upon present results is possible in this class of case, and it is a type of case which should never be seen did our methods of diagnosis enable us to get them at an early stage of the disease. It would be truer to say that there is no method in diagnosis where a disease is only realized or recognized when a patient is moribund from it.

GENERAL DISCUSSION

Mr G. I. STRICHAN (Cardiff) said that in carcinoma of the cervix they usually inserted a tube of 100 mg of radium bromide into the cervical canal and six tubes of 10 mg each into the periphery of the growth. Often another 25 mg tube was inserted well up into whichever lateral fornix appeared to be infiltrated, and all the tubes were left in position for twenty-four hours. Lately forty-eight hour applications had been used, and evidently with benefit. Preparatory douching was the rule in every case, and the

patient was sent home in a few days, to return in six weeks. It was most essential that the uterine cavity should be explored with a sound lest an unsuspected prometrya be present, also a careful examination of the fornices was necessary to find out whether inflamed appendages were present. Both these conditions contraindicated irradiation. In carcinoma of the body of the uterus, after dilatation of the cervix, two tubes of 50 mg each were inserted into the uterine cavity for forty-eight hours or one tube of 100-120 mg. In vaginal and vulval carcinoma first applications were found to be the best. In the vagina they could be held in position only by firm packing, but on the vulva fixation by adhesive stripping was satisfactory. A twenty-four hour application was necessary, but in some cases of vulval epithelioma it was painful and had to be removed after a few hours. In all these cases a douche should be ordered night and morning for three weeks in order to prevent adhesive vaginitis. In Cardiff they had treated seventy-five cases of inoperable pelvic disease with radium, but as some of these were recent the number considered was much smaller. Of this total, 40 cases were carcinoma of the cervix, of these 5 were known to have died, and 11 failed to report. Vesico-vaginal fistula had developed in 2, and in 7 no appreciable benefit had been observed. In the other 15 cases considerable improvement with cessation of symptoms had followed, constituting clinical cure. Six cases of inoperable carcinoma of the body of the uterus were treated. In each of these cases the symptoms had cleared up, and so far, after eighteen months in the last case treated, had not recurred. One case of sarcoma of the uterus was irradiated four years ago and had had no symptoms since, while she had put on considerable weight. Two cases of epithelioma of the vagina and three cases of epithelioma of the vulva were irradiated, and it had to be confessed that the results had not been satisfactory. Improvement followed by relapse occurred in each case, and of the five, three patients were now dead. Radium treatment was only in its early stages, and sweeping condemnation and undue praise were equally to be deprecated. There was much to be learnt before they could accurately assess the exact position that irradiation should occupy in the treatment of inoperable malignant pelvic disease, and they were now working to define that position.

Miss FRANCES IRENS (Liverpool) described her experience in the use of radium emanation tubes obtained from the Radium Institute, London. Her rule was to make a thorough examination under an anaesthetic, enquire away all diseased tissue, and then insert the emanation tube in accordance with the instructions sent down from the Institute. No patient had been cured, but she could testify to the enormous amount of relief given by the treatment. It had enabled women who otherwise would have been a source of misery to themselves and of offence to other people to return home and carry on their household duties to the end.

Dr HERMAN (Stockholm), in reply, said that Mr Cole had referred to the number of untreated cases. They also in Stockholm had untreated cases—about 12 per cent of all their cases. He was astonished to hear that they had found cases of recurrence after radical operation the most satisfactory cases for irradiation. In Stockholm they were of an entirely different opinion. He would like to hear more details of the method of treatment. Scar tissue was much less resistant to infections, and the risk of fistula formation in operated cases was much greater. The number of their permanent cures in operable cases (40 per cent) was about the same as the cures following radical operation. Dr Herman did not agree that sections could be taken before and after treatment with complete safety to the patient. He thought that the practice was exceedingly dangerous. He agreed as to the contraindications to radium treatment. He only gave an anaesthetic for the insertion of the radium in the case of vagus or highly nervous patients. He agreed with all that had been said about the risks of prometrya.

Mr COLE in reply to Dr Herman's remarks about the treatment applied to patients who had previously been operated on, stated that his results agreed with those of

Mr HAYWARD PINCH of the London Radium Institute. A possible explanation might be that they always used buried needles. The abdomen in these cases was now opened as a routine and the iliac vessels secured. In 60 per cent of cases when the abdomen was opened prometrya was found to be present and would probably not have been identified but for the laparotomy. The same remark would apply to prostatic disease.

AN INVESTIGATION OF CERTAIN CARDIO VASCULAR CONDITIONS IN THE PREGNANCY OF NORMAL WOMEN, INCLUDING THE RESPONSE TO EFFICIENCY TESTS

DOROTHY C HARE, CBE, M.D.,

Assistant Physician, Royal Free Hospital and Elizabeth Garrett
Anderson Hospital

THE object of this investigation is to discover if by the methods of clinical examination evidence can be obtained of changes occurring in the circulation or in the response to efficiency tests during the course of normal pregnancy, and to relate such changes as may be found to the period of pregnancy in which they occur. In order to establish the occurrence of changes a series of observations is made on individual women during the course of their pregnancy and after its termination. The patients are examined at four-weekly intervals while pregnant, and after confinement when they have returned to their usual life and activity. The patients are drawn from the ante-natal clinic of the Royal Free Hospital, by the kind permission of Professor Mellroy, and the expenses of the work of the last twelve months have been in part met by a research grant from the British Medical Association.

The conditions of examination have been kept as uniform as possible. The patients are seen in the morning between 10 and 12. A note is made of the time of breakfast and of any special exertion or disturbing factor. On arrival patients are put to rest a full twenty minutes on a couch before the taking of records is begun. Each patient included in this group of serial cases has been seen at least three times, many of them five or six times. Forty patients are included in this series, and the total number of records used is about 160. The records are not equally complete on all points. Forty-two single observations have been made, and the records of these cases have been grouped with the others according to the month of pregnancy. Fifty women medical students have been examined by the same routine tests as controls. It is hoped to make a more extended group of controls, more strictly comparable in age and work with the pregnant cases. Many cardiac patients have been examined on exactly the same lines, and these records will be made use of later.

Tests of physical efficiency have long been in use, but during and after the war many workers have attempted to standardize tests on a scientific basis. An excellent summary of the various methods employed is set out in a report by Lucy D Cripps published by the Medical Research Council last year on "The application of the Air Force physical efficiency tests to men and women." The results contained in this report of the application of tests to groups of women are referred to later in this paper, and are of great interest and value. Only certain efficiency tests have been applied to the pregnant patients. It was necessary to select easy tests to which the women would submit willingly throughout.

There are many others in the same field of investigation to whose work I would refer if time allowed. More especially I would remind you of Iellner of Vienna, Pardee in America, Robert Weiss in Prague, and Sir James Mackenzie.

The tests employed were as follows. Pulse rates lying, sitting and standing, also after an easy standard exercise, when the rates noted are (1) the maximum after exercise, (2) the rate at one and a half minutes as compared with the resting rate, (3) the total number of beats during two minutes after exercise. Blood pressures lying and sitting pressures are recorded.

The results shown in the tables and charts which follow are in general the average figure calculated from the total records obtained in each month of pregnancy. In some months the numbers of cases are as yet too small, and in some tests the range of figures is too great, for the average to be of much value. In a short preliminary paper results cannot usefully be presented in statistical form, but it is hoped to make a final report in greater detail when a larger series of figures shall have been obtained. The results so far as they go are remarkable for the high degree of "normality" and "efficiency" shown, which in more tests appears to be greater in the later than in the earlier months. The number of fine adjustments required to produce this result under the constantly changing physical conditions leaves one amazed.

These tests are calculated to discover only the end results of these adjustments, and nothing of the mechanism of production.

The Pulse Rates

CHART I—The control figures shown are the average figures published by L. D. Cripps, from observations on different groups of women, and also the figures obtained in my own series of control cases. The line shows the mean of the rates obtained in each month in pregnant women. It will be noted that only in the fourth month do these lie outside the

CHART I—Pulse rates during pregnancy

range of the control figures and there is no marked difference in the last months from the earlier figures, though the average in the ninth month for the sitting and standing rates is slightly higher than in the preceding month. The difference between the lying or sitting and the standing rate is one of the efficiency factors noted in my series of tests. It is a test of the capacity to rapid adjustment to position. It is generally held that in a normal individual this rise should not exceed fifteen beats a minute. It will be seen from the chart that the average increase is less than ten beats except in the fourth month. Examination of individual records shows that 88 per cent give a normal response and in the last two months only two individuals gave an abnormal response. The wide variation in rate seen in the fourth month needs to be corroborated by further observations.

CHART II The Individual Variation in the Resting Rate—This chart is drawn up from an examination of individual records for the highest resting pulse rate. The month in which the highest rate is found is then recorded. The chart shows the percentage indicating the highest rate to the total number seen in each month. In the first chart the resting pulse rate shows a slight dip in the fourth month; this dip appears again in the present curve. We may conclude from this chart that the quickest rate may be found in any month of pregnancy but that only 16 per cent give the maximum rate in the last month.

CHART II—Individual variations of resting pulse rate

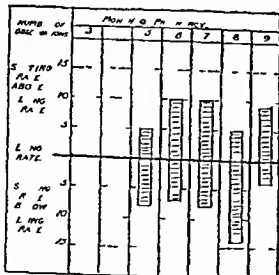

CHART III—Comparison of the pulse rate sitting and lying

CHART III Comparison of the Sitting and Lying Rates—The horizontal line represents the lying pulse rate and the length of the column above or below represents the number of individuals from the lying to the sitting position. The sitting rate was taken after ten minutes rest in that position. Ordinarily this change would cause a slight increase of rate but if the circulation is embarrassed when lying and less so when sitting the pulse would slow down on sitting up. This is seen to occur in the eighth month

in a majority of the patients, whereas in the ninth month the response to the change of position is reversed. These changes may be associated with the increased abdominal pressure and embarrassment of the diaphragm in the eighth month and the relief which follows when the head descends into the pelvis in the last weeks.

Exercise as a Test of Efficiency

Many forms of exercise have been used as efficiency tests, but it has been shown by Pembrey and Hunt that for a routine test a light exercise readily performed is of more value than a severe test. The test here used is thirty steps in sixty seconds up and down on a stool 7 inches high; it is performed to the ticking of a metronome. The normal pregnant woman does this cheerfully, even in the last weeks. The pulse rate is counted immediately after the exercise for two minutes. The pulse rates that are of chief interest are (1) the maximum rate calculated from the first ten seconds count (Chart IV a), (2) the total number of beats in the two minutes (Chart IV b), (3) the rate at one and a half minutes (Chart V).

CHART IV Pulse Rates after Exercise

The maximum rate is shown at (a). The mean rate for all the pregnant cases is 124 and for the control 126. It is interesting to note that the highest rate for the pregnant cases is in the fourth month, but there is no wide departure from the mean in any month. The total number of beats is shown at (b). These records cover so wide a range that the average figure is not of great value. The range is from 240 to 110 in controls, and from 250 to 130 in pregnant cases. When considering the higher average in the ninth month it must be remembered that although the exercise is the same there is an actual increase in the work done owing to the increase in the load carried. The weight of the patients is noted in all cases and results can be examined later from this aspect.

CHART IV—Pulse rate after exercise

CHART V The Pulse Rate One and a Half Minutes after Exercise compared with the Resting Rate—The resting pulse rate is represented by the horizontal line, and the rates after exercise are shown in percentages of the number of records above or below the previous resting rate. The normal response after light exercise may be taken as a return within a minute and a half to or below the resting rate. Pembrey and others have shown that the rate of fall depends however on the severity of the exercise even in a trained individual. It will be seen that in the earlier months the percentage of normal responses is low while in the later months 60 per cent give a normal response. It might be thought that this improvement in efficiency is due to practice in the test, but many individuals are examined for the first time in the sixth and seventh months when the response obtained is normal in a high percentage and this factor does not I think account for the whole change. It will be noted that in the control group there were over 20 per cent of abnormal responses.

CHART V—Pulse rate at one and a half minutes after exercise compared with resting rate before exercise. Percentage of records above or below resting rate. The normal response is a return to the resting rate or below.

CHART VI Blood Pressures—The readings are made by two observers working simultaneously on the two arms connected to the same manometer. The pressures are read by auscultation. It is found that the pressures both systolic and diastolic, may be highly variable in the same individual at one sitting. Precaution is taken to ensure uniformity of interpretation of the sounds. The first reading is always discarded. Then three consecutive readings are made and recorded making six records in all of which the mean is taken for use in compiling this chart. Both the systolic and diastolic curves in pregnancy show a mean rather below that of the control figures. The group of medical student controls were observed by myself and my usual assistants.

under exactly the same conditions as were used for the pregnant women. The other control figures are from the report of L. D. Cripps. The observations were made on different groups of women of varying ages none, however, are strictly comparable in age

CHART VI—Blood pressures—sitting and lying

and mode of life with the working-class housewife who forms the majority of my cases. The actual range of systolic readings is not shown on the chart but in 191 cases of pregnancy a record above 140 mm of mercury was made only four times, and records above 130 mm only ten times.

The fact that these higher readings are so exceptional reaffirms what has been stated by many observers, that a high systolic pressure in pregnancy calls for very careful investigation to exclude toxæmia. A record of the pressure should be made in the early months as a routine, or a high normal pressure may give rise to anxiety if discovered only in the later months. A patient, aged 29, had a systolic pressure of 150 mm of mercury in the fourth month, and 140 mm in the ninth month. Intervening records were rather lower. She was apparently quite healthy and had a normal confinement. The diastolic pressure curve rises in the ninth month, though not above the limit of normal control figures. A larger series of cases needs to be studied to establish this finding.

Conclusion

I have put before you in a condensed form some results which have been obtained from the examination of a series of normal pregnant women. These results show for the most part a high degree of "normality" in the adjustments of the circulation. One may say that the rate of the pulse, whether lying, sitting, or standing, is normal, and that the response to change of position is normal, though in the eighth month there is a slowing of the pulse rate when sitting as compared with lying, which may be associated with the position of the uterus and pressure on the diaphragm.

The exercise test is well performed throughout, but the return of the pulse to the resting rate after the exercise is slower in the earlier months, this may mean that the efficiency is less, but in other tests it appears that the fourth month is a period when the heart is more easily excited to a rapid rate than later in pregnancy.

Blood pressures show no tendency to rise with the advance of pregnancy and are indeed throughout on the low side of normal.

The application of the knowledge gained by physiological tests is obviously important to the better understanding and treatment of pathological conditions. It is with this goal in view that the present investigation is being carried on and that I have ventured to bring this preliminary report to you to-day.

DISCUSSION

Mr R. H. PARAMORE (Rugby) said the pulse rate and blood pressure in different periods of pregnancy were determined by many factors. Of these, the volume of the blood and the possibly changing volume of the blood (which might explain in part the low non-protein nitrogen content of the blood in normal pregnancy) was important. The speaker believed the heart hypertrophied in pregnancy. The foetus had its own circulation, and the foetal heart determined (to a large extent) that circulation, but the maternal peripheral resistance was increased by the placenta. It was an error to suppose that the maternal peripheral resistance was caused only by the (maternal) arterioles. In the state of attention (in the non-pregnant) there was an increased blood flow through the brain, this was conditioned by a tightening up of all the muscles of the body. This increased muscular tonicity caused a greater difficulty of the blood flow through the muscles (by constricting the muscular capillaries), and a greater difficulty of blood flow through the capillaries permeating the abdominal visceral mass, which was more compressed by the tightening up of the abdominal wall muscles and thoracic diaphragm. Thus a higher aortic pressure resulted, and a greater blood flow through the brain. The peripheral resistance was caused, not only by the arterioles, but considerably or to a large extent by compression of capillaries. In pregnancy the capillary resistance in the abdomen, in many cases, was increased the superficies of the abdominal wall had become much greater, and the tonicity of the abdominal wall muscles so augmented that separation of the recti occurred. A distinction between the condition of affairs affecting the circulation in primigravidae and in pregnant multiparae had not been made, but it was important. In the brief moments left for discussion it was impossible either to criticize or augment the argument, but the subject was essential to an understanding of the metabolic state of the individual in pregnancy.

MEDICAL, SURGICAL, OBSTETRICAL

THE NON-LUETIC ARGYLL ROBERTSON PUPIL

I have previously reported seven cases of Argyll Robertson pupil which had distinctive features, and in particular were not associated with syphilis. The characters were

- 1 That they were inactive to light stimulus, whether direct or consensual
- 2 They reacted slowly with convergence
- 3 Five of the seven cases were unioocular
- 4 Accommodation was intact in every case
- 5 They dilated fully with mydriatics
- 6 The knee-jerks were present in every case
- 7 In none was there evidence of parasympathetic or any other general nervous disease even after so long as thirteen, thirty-six, and forty years in three cases

It seemed probable that some at least of these cases were congenital.

Kinnier Wilson, in his excellent articles on the Argyll Robertson pupil points out that the phenomenon is seen apart from syphilis, as in epidemic encephalitis and insular sclerosis, but makes no reference to cases of this group which seem to be quite unassociated with any diseased condition. They are uncommon, and it seems worth while adding the following case to the previous seven.

A married woman aged 37 complained that in general her left pupil did not vary in size she said however that occasionally it became very large so that the eye looked like a glass eye and at other times it became very small and at either such time her sight was misty.

The right eye was normal in every respect. The left pupil was quite inactive to light stimulus whether direct or consensual it reacted slowly with convergence accommodation was intact the acuity was 6/6 the fundus was normal the pupil dilated fully with mydriatics the knee jerks were present and she was perfectly normal and healthy in every way.

- 1 *Trans. Ophth. Soc. U.K.* 1924 xlii 38 and *Medical Ophthalmology* second edition p 175
- 2 *Journ. of Neurol. and Psychopath.* 1921 li 1.

There was no evidence of acquired or congenital syphilis. She knew that the condition of the pupil had been present for six years at least, and was prepared to believe that it had been present longer than this she felt sure however, that it had not been so all her life.

A point of considerable interest was that her sister, two years younger, had a similar pupil, which she knew had been present for a number of years. I have not previously come across a case in which there seemed to be a familial tendency.

R FOSTER MOORR, F.R.C.S.

TREATMENT OF SPRUE WITH CALCIUM LACTATE AND PARATHYROID EXTRACT

The results obtained in this case of sprue treated with parathyroid and calcium lactate viz, I think, sufficiently good to be placed on record.

An Englishman born in London went to the East for the first time early in 1920 as purser in a line of ships running between Calcutta Madras Bombay and Dublin. Apart from a few months in England in the spring of 1922, he remained in this part of the world until the end of 1923 when he returned to England. While at home in 1922 he stated that he suffered for nearly two months from chronic diarrhoea for which he was treated without relief. On questioning him about his illness nothing suggestive of sprue was elicited. During his service as purser practically the whole of his time was spent on shipboard except for an occasional day or so he did not live on shore at any time. At the end of November 1924 he came to East Africa and resided first at Mombasa and then at Dar es Salaam.

On April 7th he was admitted to the European Hospital, Dar es Salaam. During the previous four weeks he had been suffering from chronic diarrhoea passing five to seven stools daily. He had been feeling generally unwell for a week and only able to do his work as a clerk in a shipping firm with an effort. The diarrhoea commenced about 3 or 4 a.m. it was unaccompanied by any abdominal pain or discomfort or by any soreness of the mouth or tongue, it had almost ceased by midday. The patient looked ill, sallow and thin. He weighed 7st 12lb, his normal weight being stated as about 9st. The stools were typical of sprue, being loose, pale, copious, sour smelling and frothy. There was no involvement of the tongue or the buccal mucous membrane.

On the next day, after a preliminary purge of castor oil a twelve day course of treatment was commenced, tablets of 1/10 grain parathyroid extract being given each night, and 10 grains of calcium lactate three times a day. The patient during this treatment was kept in bed and put on a milk diet. Improvement in the character and number of the stools was rapid and steadily maintained. From April 13th onwards he never passed more than two stools in the twenty four hours and these began to be formed on April 15th—that is, seven days after starting treatment. On April 19th small amounts of solid food began to be introduced into the dietary. On April 23rd a severe attack of subtertian malaria developed, which, although yielding readily to quinine treatment considerably retarded his convalescence. No return of the diarrhoea occurred. On May 1st soft formed stools containing a little faecal colouring matter, were being passed. On May 25th he was discharged from hospital and sent for a short sea voyage his weight then being 8st 2½lb. On his return his general condition was much improved he looked and felt well and his weight was 8st 7lb. On August 10th he returned to work at Mombasa and was enjoying good health having had no return of diarrhoea although the stools were still purer than normal, his weight was 8st 6½lb. It was unfortunate that I could not obtain any estimation of the calcium content of the blood.

I wish to thank Dr J. O. Shucore, Director of Medical Services, Tanganyika Territory, for permission to report the case.

European Hospital Dar es Salaam

THE TYPHOID BACILLUS RECOVERED FROM GALL STONES

The following case presents certain features of interest from the pathological and bacteriological points of view.

A woman aged 79 years in whom cachexia and gradually deepening jaundice was followed by death was found *post mortem* to have a large tumour growth occupying the region of the gall bladder with numerous secondary growths throughout the liver substance. Embedded in the substance of the primary growth were about a dozen small faceted gall stones greenish black externally.

Bacteriological Examination

Two of these selected at random were cut with aseptic precautions. The cut surfaces were rubbed with a sterile platinum loop which had previously been charged with a drop of condensation water from a sterile agar slope and a slope culture was made. Numerous colonies were present on the slope after twenty-four hours incubation. These were rubbed off with a platinum loop and successive streaks were made on a plate of MacConkey's medium (lactose taurocholate neutral red agar) after a further period of twenty-four hours incubation numerous

small pale colonies were present on the plate four of the 9 were subcultured in broth, and were found to be Gram negative motile bacilli which ultimately gave the fermentation reactions characteristic of *B. typhosus*. A further subculture tested by Dreyer's technique with standard *B. typhosus* antiserum issued by the Oxford Laboratories, agglutinated up to a serum dilution of 1 in 1,000. The identity of the organism was therefore held to be established.

Cultures from both large and small bowels taken at the *post mortem* examination were negative. There was no definite scarring from ulceration in either bowel. The tumour was an adenocarcinoma.

The only intestinal trouble recorded in this patient's case was an attack of "mild dysentery" in 1911. Apparently no bacteriological investigations were carried out then, but it is significant that she suffered afterwards from transient attacks of jaundice.

The association of gall stones with typhoid fever has long been known, and *B. typhosus* has on several occasions been isolated from the interior of gall stones as in this case.

We are, I think, justified in concluding that the sequence of events in this patient was (a) typhoid fever, (b) gall stones, (c) carcinoma of the gall bladder.

I am indebted to Dr C. I. Bunnidge, deputy medical superintendent, for permission to publish these notes.

Pathologist, Devon Mental Hospital Exmouth

RAW PANCREAS BY MOUTH COMPARED WITH INSULIN

I HAVE noticed the controversy going on between Mr R. D. Lawrence (June 13th, 1925, p. 1108) and others with reference to the efficiency of raw pancreas by mouth, and perhaps the following charts, which I believe are self-explanatory, will help to clear up the matter.

The first patient A. H., aged 31, a felt hat maker was sent into hospital practically comatose; he has now gained 10 lb in weight and returned to work, using no insulin only raw pancreas.

The second patient Miss M. E. D. aged 34 has had pulmonary tuberculosis for at least six years and only recently had symptoms of diabetes mellitus. She has greatly improved—has gained 6 lb and feels well. She is taking pancreas using 0.25 ccm insulin daily when pancreas is not available.

The cases, I believe, are more interesting because of the relative youth of the patients. The pancreas is prepared by first putting it in brine for 24 hours and then mincing with raw green lettuce and then mincing. The patients assure me that they have become, eress, etc. The patients mixture of which they take some quite accustomed to the meal. Neither patient is now a tablespoonful before each meal. I have to thank the pathologist at the Preston and a strict diet. I have to taking the blood sugars.

VACCINATION AND SMALL POX ON THE WITWATERSRAND

THE experience of the Witwatersrand, including Johannesburg, during the 1905-6 small-pox epidemic produced striking and compelling mass evidence of the preventive value of vaccination, the publication of which has hitherto been overlooked. The Europeans, and especially the "coloured" (Malays, Indians, and half-castes), were very indifferently protected by vaccination, which was not then compulsory amongst them; the native workers (but not their women and children) were compulsorily vaccinated.

Chinese miners, who possess no racial immunity against small pox, had been vaccinated at the ports of embarkation, and any unsuccessful or doubtful "takers" were vaccinated again at Durban.

The following are the official figures

	Population	Small pox Cases ¹	Proportion of Cases to Population
Europeans ¹	116 670	149	1 in 783
Coloured ¹	14 357	35	1 in 410
Natives Males 163 000 ² Females 8 612 ²	163 611	28	1 in 6 021
Chinese ³	46 772	Nil	Nil

¹ Census 1904. ² Native Affairs Department return. ³ Chamber of Mines Medical Officer of Health's records.

The fact that not one single case occurred amongst the 46,772 well vaccinated Chinese who worked alongside the Europeans and natives is notably significant.

Again (as shown by the Government mining engineer's return), at the Village Main Reef Mine the white workers numbered some 308 and were mostly indifferently vaccinated; the natives averaged 2,233 and were well vaccinated. Ten cases occurred amongst the 308 white men, but none amongst the 2,233 natives who worked with them.

Reports of Societies.

EARLY TREATMENT OF MENTAL DISORDERS

A joint meeting of the Section of Psychiatry of the Royal Society of Medicine and the Medical Section of the British Psychological Society was held on October 28th, under the chairmanship of Dr R. H. Cole, to discuss the early treatment of mental disorders.

Physical Factors

Sir MAURICE CRAIG said that in mental disorder physical factors were as important as psychological factors, if not more important, and at present it was the physical factors which were again being emphasized in psychological medicine. Long experience had taught him the primary importance of disturbed emotion, but he had also learned that there was something which prepared the way for abnormal emotional activity—namely, a general hypersensitivity of the organism. This affected both mental and physical reactions, and brought about fatigue, whereupon the organism became subject to toxic influences. There were cases in which emotional shock seemed to be the only exciting factor in mental disturbance, but in the majority of instances the severity of the symptoms would largely depend upon the preceding sensitivity of the nervous system. With regard to psycho-analysis, it was increasingly evident that the teaching of Freud was more valuable as a factor in education than as a basis for treatment. He was aware that many persons had had their symptoms relieved by psycho-analytical methods of treatment, but the question was whether the majority of these persons would not have derived the same relief from other methods, with less expenditure of time. He had long been in doubt whether repressions and forgotten conflicts were as impor-

tant as the Freudian school supposed, emotional reactions, in his opinion, were much more likely to bring about mental disorder. No one method of psychotherapeutic treatment could be regarded as all-sufficient. He went on to speak of the many conditions on the physical side which called for treatment in relation to mental disturbance. It was a matter of common experience that mental disturbances resulted from toxæmia, but the very striking effects which might follow from what appeared to be quite insignificant toxic causes were only beginning to be appreciated. To employ purely psychotherapeutic methods in a toxic condition was to waste time, and perhaps to endanger the life of the patient. Of recent years there had been overwhelming evidence of the toxic effects on the nervous system of the organism which gave rise to encephalitis lethargica. Again, there were persons who had an idiosyncrasy with regard to certain foodstuffs, he had seen epileptic fits and mental confusion follow the ingestion of eggs, and three cases of delirium supervened upon a meal of mushrooms. The part played by the endocrine glands had also to be kept in mind. Finally, he touched upon sleeplessness. Some persons were much more intolerant of lack of sleep than others, indeed, there were individuals who became definitely insane within a few days if sleep was not obtained. Sleeplessness was not treated in a systematic way. Owing to undue timidity, hypnotics were withheld. The chief objection to hypnotics was the fear of inducing a habit, but experience had taught him to be much more afraid of the effects of sleeplessness than of the almost negligible danger of addiction. It was continually being urged that this or that drug should be added to the Dangerous Drugs list, either because of the danger of addiction, or because the drug might be used for self-destruction. Some medical men thought of sleeplessness only in terms of bromides. Bromides were liable, however, to damage the lining of the stomach, and in large doses often led to great confusion of mind. He had not infrequently been called in to consider the certification of a patient whose most urgent symptoms had resulted from the administration of bromides. Of course, more especially in small doses, these drugs had a role of great value in medicine, but their value in sleeplessness was much more doubtful. The drugs of the barbitone group had come in for a good deal of criticism, but in his practice dril and medinal were the drugs which he had found to give the best results in sleeplessness.

Psychological Factors

Dr WILLIAM BROWN agreed that in all mental disorder there was a physical disturbance, however slight, and in the treatment of such disorder it was obviously necessary as far as possible to deal with that physical disturbance directly. Experience showed that a great deal of mental disturbance which might become permanent followed upon infection. A disturbance of the endocrine glands also had a pronounced reaction on the functions of the nervous system. Infection and toxic absorption seemed to react primarily upon the thyroid gland, and through it influenced the nervous system, and so the mind. Fatigue and physical exhaustion might be factors in mental trouble, and these should be dealt with on the physical side by prescribing rest. At present, however, there seemed to be little danger of these physical factors in mental disorder being underestimated, the danger was on the other side—that medical men should neglect the psychological avenue of approach. In many forms of mental disorder the causal factor was more directly psychological, and in most cases there was an interaction of mental and physical factors. So far as the physical factors could be demonstrated they should be dealt with along the appropriate physical lines, but on the mental side the disturbance should be dealt with on psychological lines, and that was where the real problem of mental disorder came in. The distinction between so-called functional disturbance and organic or structural change was important. It might be assumed that in nervous illness in which there was organic or structural change mere correction of function would be inadequate, but the difficulty of such a view was that a disturbance of function could hardly be conceived without involving some disturbance of structure. All that could be said was that if a disease was predominantly functional it was specially amenable to psychological treatment which had the effect of altering function.

Dr R H CORE (in the chair) said that he had a strong objection to placing physical and mental treatment in antagonism. If there was any physical disease that ought to be treated, and the mind of the patient ought to be treated at the same time. The mental state of the patient was probably a counterpart of his physical state.

Openers' Replies

Dr MAURICE CHASE, in taking up the point raised by Dr Stoddart, said that he did not apply the term "neurologist" to himself, and he objected to "chemist" and other terms, preferring simply the term "physician." These details and separations had done much harm. From the way in which psychology had been referred to that evening it might be supposed that the analytical school was the only school of psychological thought. There were plenty of other schools and methods. One of his objections to the psycho-analytical school was that it always took one view of the patient from the very beginning. He could anticipate the psycho-analyst's findings with regard to any patient who came to him. When the psycho-analytical method first came to this country, he supported it. He was more doubtful now, because it had cut in some respects across his own experience. As soon as psycho-analysts had made their case good he would be with them again, at the moment they had not made it good. They had done a certain amount of good work, but not better than other people. He added that lately he had been following up manic depressive cases very closely, and he believed he had arrived at some useful conclusions as to treatment. These might be the subject of a later paper, but here again he had proceeded along the physical, not the psychological, side.

Dr WILLIAM BROWN claimed for psycho-analysis, quite apart from the extent to which it fulfilled its promise of improvement and cure, that it gave a deeper insight into the nature of mind and the way in which the mind worked. But that was quite a different matter from accepting the findings of many psycho-analysts. The general impression he received, after analysing for some years, was that one was not forced to accept the Freudian doctrine of the sex instinct in its completeness, in the other fundamental instincts there was sufficient to go upon in an exploratory way, though no doubt all instincts came from one root. He defended the use of hypnotism, which, if used carefully, with due regard to the necessity for reassociation, gave definite results.

PLANT POISONING

The first meeting this session of the Section of Comparative Medicine of the Royal Society of Medicine was held on October 28th, the President, Mr F T G HOBBS, in the chair, drew attention to the rapid growth of the section, which was now one of the largest in the society, with a membership of nearly 200.

Dr W H ANDREWS read a paper entitled "Some recent advances in our knowledge of plant poisoning." He pointed out that knowledge of the diseases due to plant poisoning—more especially in this country—was in a far from satisfactory state. Many plants were suspected of being poisonous, and, indeed, it was taught in toxicology that they were poisonous, although no proof of this existed. Others not so regarded were, he was sure, toxic. It was not sufficient merely to suspect a plant, proof was necessary, and he showed that much confusion of thought existed on the subject. Lathyrism, a condition considered due to poisoning by the seeds of *Lathyrus*, was in reality caused by a weed, the seed of which was included with the others as a contamination. Again, it was known that in some cases one or two cereal beans would produce poisoning, while in other places children ate them with impunity. He considered that this was because several different species were in existence under one and the same name. Climate and soil caused plants to have different effects. He reported a case where the same plant on the same farm grew in two fields, one of black earth and the other of red, the plant growing on the red soil contained a much higher proportion of the toxic principle than did the plant on the black. One

of the most interesting features of plant poisoning was the occurrence of "latent" periods, up to three months in some cases. These were not due to cumulative action of the poison, because the animal could be removed from the affected area after feeding and the symptoms would still not be seen until a period afterwards. What made animals eat poisonous plants? In some cases it was undoubtedly due to lack of other herbage, to drought, or to overcrowding. In other cases it was probably inexperience. Native animals had learned to dislike the plants, while imported stock did not know the difference between the good and the bad, and paid the penalty of their ignorance. Dr Andrews in conclusion, suggested that investigations into plant poisoning should proceed in three steps. First of all a biological inquiry should be made to determine whether the plant was really poisonous, and, if so, in what circumstances it was toxic and to what animals. Then the chemist should attempt to isolate the toxic principle, and finally, the pharmacologist should investigate the action.

Professor A J CLARK, opening the discussion, drew attention to parallel cases of latent periods with certain mineral poisons. He believed that people were only now dying from TNT poisoning though it had been contracted during the war. A point of interest also was found in the feeding of goats with thyroid extract. A single large dose would not produce any effect, the same quantity, fed in small portions over a period, produced symptoms. He believed that this was due to the fact that only a certain amount could be absorbed at any one time, and the surplus of the single large dose was eliminated before it could produce any result.

Dr P MASON-BARR pointed out that a form of emphysema of the liver in India was probably due to plant poisoning; the use of alcohol could be ruled out in this case. A similar cause might be the key to the problem of pellagra. Dr Andrews had indicated that a certain plant in Australia after a latent interval, caused a skin sensitization which only had effect when the skin was exposed to the rays of the sun after shearing, etc. This was an interesting parallel with what occurred in pellagra, where the characteristic skin pigmentation was found only on the parts of the skin exposed to the light. Mice and vitamins could almost certainly be ruled out as etiological factors, and he suggested that the cause of the disease might well be a plant poison.

Mr STOW, a veterinary surgeon, reported the infection of himself by swine erysipelas. He explained that he had made a *post-mortem* examination of two pigs of a litter which had died after very indefinite symptoms. The pigs were black, and so the skin lesions characteristic of this disease were not visible. He wounded his hand during the examination, and, although he treated it with iodine, a painful swelling developed which disappeared in a few days, to be succeeded by others in other parts of the hand. This had happened a month ago, and the lesions were still present. He had no doubt now that the disease from which he was suffering was swine erysipelas.

DIATHESIS IN CHILDREN

At a meeting of the Pathological Society of Manchester on October 21st, Professor E D TELFORD in the chair, Dr C P LAPAGE read a paper on diathesis in children.

Dr Lapage said that the diathetic state was not acquired; it was an inherited peculiarity of constitution which could not be eradicated though it might become quiescent. An acquired condition such as rickets was not a diathesis because such a state could be cured and was not a lifelong condition. He defined diathesis as being a state of the human organism in which there was an inherited peculiarity of constitution, so that the individual tended to exhibit either certain reactions in response to irritating factors or a certain weakness of resistance. It was familial rather than racial or national. He dealt chiefly with two diatheses, the exudative and the nervous, and first referred briefly to rheumatism and tuberculosis and the various specific diatheses. He emphasized the fact that individual children developed very much in their reactions to environments and infections. A few children might be regarded as showing

the tuberculous diathesis, but most children who had the tuberculous aspect were examples of no special diathesis, and had developed the appearance because of their infection and their struggle to overcome it. Rheumatism was common in the reddish-haired type and there might be a special liability to rheumatic fever in such families. The exudative diathesis was a very important factor in determining the reaction of children to disease and to faulty metabolism. Asthma, eczema, hay fever, and angio-neurotic oedema were the well known signs of it, but cold dyspepsia, milk intolerance, urticaria, and eczema were common in infants with this diathesis and in later childhood. In addition to eczema and asthmatic or catarrhal signs, there might be cyclical vomiting, mucous colitis, and other conditions much resembling gout in adults. Children of this exudative diathesis were of the pale lymphatic type, and were restless and irritable. The question of nutrients was important in the production of signs of the diathesis. The individual was exudative and might be sensitized. External nutrients were foreign proteins derived from animals, plants, food, or bacteria, metabolic faults associated with mineral salts, acids, fruits, and wholemeal breads, climatic factors related to bracing seaside places and east winds. Internal nutrients arose from infections of the respiratory, digestive, or other systems, and also from infected lymphatic glands. The diathesis of lunacy and of mental deficiency was well known, and the epileptic diathesis was common, there were, however, many cases of acquired epilepsy. In the neurosthenic diathesis the child had a weak spot in the reactions of the nervous system, and, consequently, if there was any lowering agent, such as infection or overstrain, then disturbed nervous reactions, tachycardia, irritability, moodiness, various phobias, night terrors, and even fits might occur. Illustrative cases were described to show the phobias to which children were liable, and, in addition, as illustrating the nervous diathesis, the occurrence of special nervous signs in infancy was cited. Babies with pyloric spasm were of the 'nervy' type, and in some babies the great difficulty in feeding was due to their nervousness. Genuine hysteria might be present in infants. On investigating the family history a nervous element was usually found. There were various other well known specific diatheses, such as haemophilia, and progressive muscular atrophy. The intention of the paper was to bring out the differences in the endowment of different children, and to indicate the importance of taking these into account in the study of disease.

BRITISH ORTHOPAEDIC ASSOCIATION

The annual meeting of the British Orthopaedic Association was held on October 23rd and 24th in Manchester. The first morning session was held in the University Medical School, when Sir ROBERT JONES gave a presidential address which was reported in our last issue (p. 789).

Fractures in the Region of the Ankle-joint

Mr HARRY PLATT introduced a discussion on the above subject, dividing the fractures into two groups (a) fractures of the leg bones, (b) fractures of the astragalus. After reference to the writings of Dupuytren, Astley Cooper, and others, in which incomparable descriptions of these injuries were to be found, he reviewed in full detail the mechanism of production of ankle fractures. The merits of a classification based on mechanism were considered, and as an alternative grouping a simple anatomical scheme was suggested. The statistics of any large series of ankle fractures showed that 50 per cent of the cases were combined injuries of the tibia and fibula. The oblique fracture of the lower end of the fibula produced by external rotation of the foot on the leg was the commonest lesion. In the majority of ankle fractures there was little or no primary deformity. Unmistakable or gross deformity was present in some 25 per cent of the cases. At the same time the importance of the minor degrees of displacement was not sufficiently appreciated. Failure to recognize marked deformity accounted for many of the unfortunate results. In the treatment of recent fractures the speaker was confident that conservative measures of reduction and retention gave functional results of the highest standard, and in his opinion primary operative intervention should be reserved for the occasional fracture in which manipulative

reduction failed to give perfect readjustment. Mr Platt's views were supported by the information obtained from an inquiry into the late results in a personal series of 116 ankle-joint fractures seen during the four-year period 1921-24. Some of the results obtained were illustrated by lantern slides. The treatment appropriate to old fractures was outlined, and the introduction closed with a brief reference to fractures of the astragalus.

In the discussion which followed Mr W. H. TAYNOR demonstrated the results of operative treatment of recent ankle fractures, a method which he advocated is a routine in all fractures with displacement. He stressed the importance of restoring the alignment of the fibula, and the "fit" of the ankle mortise.

Mr H. A. T. FARRAR believed that a more frequent resort to primary operation would give a shorter period of incapacity. He also regarded minor degrees of displacement as important, and in such cases he did not feel that it was always easy to obtain readjustment by manipulative methods.

Mr W. A. COCHRAN quoted a series of 50 cases from the Edinburgh Royal Infirmary which illustrated the satisfactory functional and economic results of conservative methods of treatment. The details of reduction and the application of a plaster of-Paris cast were described.

Mr S. T. INYR had followed up the results of ankle fractures in the Royal Victoria Hospital, Belfast, for the two-year period 1923-24. Out of 77 cases examined 68 were found to be working. In this series open operations were carried out in four cases only, the remainder were treated by manipulative reduction and splinting, following the methods introduced by the late Professor Gordon.

Mr R. OLLIVAN expressed himself as in favour of conservative methods of treatment as a routine, but with a prompt resort to primary operation when a satisfactory position could not be obtained by manipulation. The radiograms of a number of cases with extreme displacement treated by manipulation were shown, the patients having returned to laborious duties.

The afternoon session was held at the Ancoats Hospital, where Mr H. PLATT operated before the members of the association and afterwards gave a demonstration of patients. An exhibition of remedial exercise work was also given in the gymnasium. The association dinner was held at the Midland Hotel, and was attended by seventy-eight members and guests.

The morning session of the second day was held at the University Medical School. The programme consisted of the following short papers: (1) Renal calculi, by Dr G. ASHCROFT (by invitation), (2) Operative measures in drop-foot, by Mr R. OLLIVAN, (3) Injuries of the atlas and axis, by Mr G. JEFFERSON, (4) Much-foot, by Dr MARK JANSSEN, (5) A bone graft for sacro-iliac fixation, by Mr P. J. VERULM, (6) Demonstration on the making of cork supports for metatarsalgia, by Dr J. B. MERRILL. A series of dissections and specimens illustrating the surgical anatomy of the peripheral nerves and sympathetic system from the Department of Anatomy (Professor J. S. B. STOPFORD) were inspected.

The afternoon session was held at the Royal Manchester Children's Hospital, where Mr R. OLLIVAN operated before the members of the association and afterwards gave a demonstration of patients.

GASTRIC FUNCTION IN RELATION TO SYMPTOMS

The first meeting for the session of the Cradiff Medical Society was held at the College Newport Road, on October 13th, when Dr R. CARMON delivered his presidential address on some aspects of gastric function in relation to symptoms.

Taking Rylo's classification of dyspepsia as a basis, he reviewed the functional and organic disorder and emphasized the similarity of subjective symptoms arising from both. He described many of the prevailing views on the motor, secretory, and sensory functions and contrasted them with those which had hitherto prevailed and been taught. The methods of investigation by x-ray examination of a barium meal, and by fractional gastric analysis,

were compared to show how different methods required different interpretations, and how in certain conditions motility might appear delayed by the former and hastened by the latter even allowing for the different time standards. Dr Cameron described particularly how tonus and peristalsis in conjunction with muscular sensibility, might give rise to such normal sensations as resulted from fullness or emptiness of the stomach and other hollow viscera. He reviewed the work of Carlsson on hunger and appetite, and pointed out that the factors producing normal sensations might, when exaggerated, lead to those conscious responses which were recognized as subjective symptoms. Huist's important contributions to this subject, in displaying an sensory response of the gastric mucous membrane to varying stimuli, in demonstrating reflex hyper-tonus in response to local and distal irritation, and in establishing this as a cause of delayed pain, and his theories on conditions supposed to arise from exaggerated or diminished gastric acidity, were described. The researches of Bennett and Ryle on fractional gastric analysis were dealt with to show that extreme variations of acidity occurred without any gastric symptoms being evident, and apparently without any disturbance of metabolism. In a series of mental patients—free from any stomach symptoms—which the speaker had personally examined there was a definite percentage at each end of the scale—namely, with achlorhydria or with hyperchlorhydria. Similar variations of tonicity occurred in any series of healthy stomachs.

Dr Cameron's conclusions, drawn from recent work on gastric function in health and disease, were that normal sensations resulted from tonus and tension of the muscle, and that subjective symptoms were most easily explained on the same basis.

Reviews.

THE MECHANISM AND GRAPHIC REGISTRATION OF THE HEART BEAT

THE unremitting labours of the staff of the department of cardiac pathology in University College Hospital Medical School in elucidating, on a scientific basis, the intricacies of the cardiac action are reflected in the presentation of a new edition of *The Mechanism and Graphic Registration of the Heart Beat*, by Sir THOMAS LEWIS.

It is unnecessary to give in detail the general arrangement of the book, which is already well known and is accepted as the standard work on the subject in the English language. The plan is, in general, that of previous editions, but the text has been subjected to revision and much new material has been incorporated. The present volume is larger than its predecessor by 62 pages of text, and has 51 new illustrations, the bibliography now contains over 1,000 references. Chapters which appeared in the last edition have been reviewed in the light of the most recent research, and several new chapters have been added.

Of the new matter perhaps the most important is that dealing with the nature of auricular flutter and auricular fibrillation. The view of Mines that persistence of fibrillation in the ventricles is associated with "circus movement" was discussed in the previous edition, and only an inset recorded the fact that the author, as the result of experiments then recently completed, had obtained evidence that auricular flutter was due to circus movement, and that auricular fibrillation resulted from depressed conduction. The work upon which this opinion was based, with much additional evidence, is incorporated in the chapters which deal with these two disorders. As an example of scientific accuracy and logical deduction applied to the investigation of pathological problems we feel that the author's work on circus movement should be read by all who are interested in the advance of medical science in any of its various branches. Further new matter will be found in the chapter dealing with the influence of the vagus and of quinidine and digitalis upon flutter and fibrillation. In the short

section on the response of the ventricle to fibrillation of the auricle, the statement that "the theory of circus movement" fully explains the characteristic response of the ventricle" might have been preceded by a more detailed exposition.

The chapter on the refractory period of heart muscle and its relation to conduction affords explanations which will go far to illuminate some otherwise obscure problems. Fresh light is also shed on the mechanism of alternation. In an interesting section the puristolic theory is discussed.

Whether viewed as the latest word to date on the mechanism of the heart beat, as an incentive to further research on cardiac problems, or as a vindication of the value of graphic methods, this book must be accorded a supreme place in medical literature.

In the reproduction of the numerous graphic records the publishers have maintained the high standard of excellence which has characterized this book since its first appearance.

FIBRINOGEN

In his book on *The Action of Antifibrinogen Serum on Red Corpuscles* Dr DAVIDE defines fibrinogen as the albuminous product obtained by the addition of an equal volume of saturated salt solution to oxalated or citrated blood plasma, and argues that it is far from being a single well defined protein or chemical entity. The fibrinogen thus prepared from the plasma of half a dozen different mammals was used, by intravenous injection, for the immunization of various animals, chiefly rabbits. The antifibrinogen serum taken from these rabbits was found to be very destructive to the red corpuscles when injected into other animals. Dr Davide here used guinea-pigs for the most part. The antifibrinogen sera have no erythrocyte-destroying action on animals of a species differing from that which supplied the fibrinogen (that is, on heterologous animals). But *in vitro* the reactions are different, and the author devotes most of his volume to the heterologous haemolysis that occurs when the red corpuscles of the sheep are exposed to the action of the serum of rabbits immunized with the fibrinogen of man, guinea-pigs, or dogs. The immunization of horses, sheep, and goats with rabbit fibrinogen does not generate sheep haemolysins.

In explanation of the fact that specific haemolysins are thus not produced by all kinds of fibrinogen, Dr Davide assumes that the fibrinogens of different animals must have reached different stages in the course of development, and must have diverged from the parent substance to different extents. He finds that the most easily precipitated and thus the least dispersed fibrinogens most easily produce haemolysins, the most dispersed fibrinogens do not produce these antibodies. His book should be of interest to experimental pathologists, it shows that the study of haemolysis that has been in progress for over a quarter of a century is still well worthy of prosecution.

DIATHERMY IN PNEUMONIA

ALTHOUGH Dr H. E. STEWART's *Diathermy and its Application to Pneumonia* is chiefly directed to one disease, it is not without interesting references to others—for example, a chapter is devoted to surgical diathermy, sometimes called endothermy, in the treatment of malignant tumours, and there is an account of general diathermy or autocondensation, which is mainly used to reduce high arterial blood pressure. It is pointed out that when the blood pressure has been brought down to the level appropriate for that individual, although it may still be considerably above that usually calculated as the normal, it can generally be kept within these limits by one or two applications a month.

A notable feature about this book is the modest and open-minded manner in which the data in favour of the

Action of Antifibrinogen Serum on Red Corpuscles. By Hans Davide. Acta Medica Scandinavica Supplementum. A.I.L. Stockholm. P. A. Norstedt and Söner 1925. (Med. 8vo pp. 123.)
Diathermy and its Application to Pneumonia. By Harry Eaton Stewart. W. D. New York. Paul B. Hoeber Inc. 1923. (Cr. 8vo pp. xvi+210. 45 figures. 15 charts. 3 dollars.)

The Mechanism and Graphic Registration of the Heart Beat. By Sir Thomas Lewis, M.D., F.R.S., F.R.C., D.Sc., C.P.E. Third edition. London: Shaw and Son, 1925. (Cr. 4to pp. xiv+529. 400 figures. 42. 10 net.)

value of diathermy in pneumonia is presented. The method is described in minute detail, and the contraindications and precautions, such as attention to subjective tingling or burning sensations, to be taken in order to avoid untoward effects, are set forth in clear language. It is definitely stated that with proper technique no harm can be done to the patient, as diathermy lowers the blood pressure it was at first thought that this might be a contraindication to its employment in pneumonia, but experience has shown that this objection does not hold good.

Diathermic heat is developed more or less centrally in the tissues, and thus differs from methods in which an attempt is made to drive heat through the skin and subcutaneous tissues into the deeper parts of the body. A temperature of 110° F., or more, produced locally in the lung is thought to dilate the blood and lymphatic vessels, perhaps to "melt" the exudation, and to inhibit and to some extent destroy the micro-organisms. About seventy cases of all forms of pneumonia, many of them in the United States Marine Hospital No. 21, New York, were treated by diathermy, and in 97 per cent the temperature began at once to fall by lysis, and the symptomatic relief was almost always so remarkable that this alone would justify its use, provided no contraindications are noted. So far no case in which diathermy was started before the third day of the disease has proved fatal, and the results yielded by diathermy are described as at least as good as those obtained by the use of serum in cases due to infection with pneumococcus Type I. Diathermy has the advantage that it does good in pneumonia due to all types of pneumococci and streptococci. This new form of treatment, so frankly presented by the author, certainly deserves attention and further trial.

MINOR SURGERY

HEATH'S *Minor Surgery and Bandaging* is a classic in its way, and it is so well known, and has been so extensively used by generations of students since its first appearance in 1861, that anything in the way of comment on it appears to be almost superfluous. Those who had the privilege of listening to Christopher Heath will readily recall, not only the vigorous and practical character of his teaching, but more especially the extraordinary colouring that his personality imparted to it. He had the power of impressing his hearers to such a degree that years afterwards the very words, tone of voice, and gesture seemed to recur automatically. The preparation of the eighteenth edition of the work has fallen into good hands, and Mr GWYNNE WILLIAMS has wisely endeavoured to retain the original character of the book, making only such innovations as the progress of surgery rendered necessary. The technique of asepsis has not materially altered since the last edition, and the treatment by surgical methods of infected wounds is much the same as it was left by the war, but the description of the infectious of the fingers and hands has required some alteration, in view of the increased knowledge of their pathological anatomy, as systematized by KAYE. The section on the non-operative management of fractures has required considerable alteration, and an account of Delbet's method of treating fractures of the tibia and fibula has been included. In view of the valuable assistance afforded by skeletal traction in the treatment of fractures of the lower limb, a short description of the simpler methods has been inserted, and somewhat more emphasis is laid on the use of plaster of Paris splints with the suggestion that their employment might advantageously be extended. The value of blood transfusion in certain cases is now recognized and an account of the citrate method has accordingly been included. The chapter on anaesthesia has been extended by the addition of short descriptions of the methods of gas and oxygen anaesthesia and sacral anaesthesia. The editing of this eighteenth edition has doubtless been a labour of love and, as to its efficiency, there can be no question that Christopher Heath would approve the result and thus, after all, is the proper standard to have aimed at.

Mr FIFIELD'S *Minor Surgery*, while excellent in many ways, may be said to lean too much towards the academic aspect of the subject. It forms a well illustrated catalogue of the various instruments employed in minor surgery, with the necessary details as to how to use them, and it provides a good account of the methods and numerous appliances used in the setting of fractures, with illustrations and the names of the different splints. The minor operations have been well chosen and well described. One of the best chapters is that on infection of the hand and its treatment. Bandaging has been adequately dealt with. A chapter at the end of the book discusses anaesthesia—general, local, and regional. One minor criticism of the book is that it is not practical enough. It describes well what ought to be done, but offers insufficient information as to what should not be done. As an illustration the use of Junker's splinter may be cited. Three important points demanding attention are mentioned, and then appreciation will obviate accidents, provided the apparatus is in good working order. The more important detail is to tell the inexperienced how to test the apparatus before use. The first chapter could be profitably enlarged and differently arranged, the alternative method of treating retropharyngeal abscess might have been mentioned, and in the directions for passing a catheter a word might have been said as to how urine should be drawn off in cases of retention. The book contains much useful information, and Mr FIFIELD should feel encouraged to look forward to another edition.

SARCOMA OF BONE

Bone Sarcoma. An Interpretation of the Nomenclature used by the Committee on the Registry of Bone Sarcoma of the American College of Surgeons is a reprint (with corrections) of an article by Dr COOPER in the February number of the *American Journal of Roentgenology and Radium Therapy*, and is produced in the beautiful style characterizing Paul B Hoeber's publications. The aim of the committee mentioned in the title consisting of Dr James Ewing, the author of *Neoplastic Diseases*, Dr J C Bloodgood of the Johns Hopkins Hospital, and the author, is to arrive at a simplified, uniform, and universally adopted nomenclature of sarcomas of bone, and they are therefore open to suggestions for a better one than that tentatively put forward here. For this purpose official nomenclature sheets have been circulated for the registration of tumours of bone with the following list of names: metastatic tumours, periosteal fibrosarcoma, osteogenic tumours, inflammatory formations, benign giant cell tumours, angioma (benign and malignant), Ewing's tumour, and myeloma.

The inclusion of inflammatory swellings and of admittedly innocent growths certainly seems to confuse the issue without any compensating advantages. Inflammatory conditions are inserted in the middle of the list because on the one hand excessively exuberant callus may approach malignant osteogenic sarcomas, and on the other hand because of the borderline conditions, such as osteitis fibrosa and cysts, between inflammatory and neoplastic formations. Benign giant cell tumour is Bloodgood's name for the familiar myeloid growth shown more than twenty years ago by Sir John Bland Sutton to be non-malignant though locally distinctive and therefore not meriting its usual title myeloid "sarcoma." The success of early exposures in producing fibrosis and ossification of these growths is mentioned. The term "Ewing's tumour," introduced in spite of the describer's protest, is applied to a growth which always involves the shaft and its whole thickness, is composed of small round cells gives a characteristic longitudinal, not radiating, striation in radiograms, and yields temporarily to a ray, but has a grave prognosis. Ewing regarded it as an endothelioma, but other members of the Registry are inclined to put it among the undifferentiated sarcomas of the osteogenic group.

The longest account is that of the osteogenic tumours,

Minor Surgery By Lionel R FIFIELD F.R.C.S. Eng. London. H K Lewis and Co. Ltd. 1925. (Cr. 8vo pp. x+431. 275 figures. 12s. 6d. net.)
Bone Sarcoma. Nomenclature used by the Committee on the Registry of Bone Sarcoma of the American College of Surgeons By E. L. COOPER. Paul B Hoeber, Inc. 1925. (Cr. 8vo pp. x. 2 dollars.)

* *Minor Surgery and Bandaging*. Eighteenth edition. By GWYNNE WILLIAMS. M.S. F.R.C.S. London. J and A Churchill. 1924. (Cr. 8vo pp. viii+422. 239 figures. 10s. 6d. net.)

which may be innocent or malignant, they are supposed to be derived from the cellular aneasios of bone, cartilage and fibrous tissue. The malignant forms select the ends of the bones and commonly are both endosteal and periosteal. Dr Codman doubts that these osteogenic sarcomas are ever periosteal only. Other forms of the osteogenic sarcoma are the "undifferentiated," composed of round cells without any tendency to form bone or fibrous tissue, and the telangiectatic, with an unusually bad prognosis. The last group is that commonly called multiple myeloma.

The task undertaken by the committee is of the nature of a collective investigation, and appeals for data from chemists, pathologists, and radiologists. Its aim, therefore, is admirable, but the tentative classification adopted does not seem an improvement on that in common use, varying, as of course it now does, in the hands of different pathologists.

THE YOUNG DELINQUENT

"In 1735 Mary Wotton, a little girl of 9, who had been apprenticed fourteen months before by the parish to the wife of a certain John Easton, broke open her mistress's drawers, took twenty seven guineas, ran away, and was found in Rag Fair. She was sentenced to death." The quotation is taken from the book of Mrs Dorothy George, an *London Life in the XVIIIth Century*, the record of the case is to be found in the London Sessions Papers of July, 1735. It was not exceptional. If there be anyone who is to-day a pessimist on the state of social order of this country, or indulges in a fit of the "blues" at the records in the daily press of strikes, thefts, and crimes of violence, he may be recommended to read this book. By contrasting to-day with these records of the past he will find much to make him an optimist. This book, which is amply documented, gives a picture of the times which is enthralling and terrible. Francis Place, himself one of the people and one who had suffered greatly from the spirit of the times, writes in his autobiography: "The circumstances

I have mentioned relative to the ignorance, the immorality, the grossness, the obscenity, the drunkenness, the dirtiness, and the depravity of the middling and even of a large portion of the better sort of tradesmen, the artisans, the journeyman tradesmen of London in the days of my youth may excite a suspicion that the picture is a caricature." But the truth of his testimony is established. Further, he found much in his times to show that even then a steady improvement had been brought about in manners and outlook upon life, and that this was due to an intense sense of personal freedom in the Londoner and to his share in the heritage of British liberty. And "freedom being primarily a state of mind, we must recognize the undoubted fact that this sense of personal liberty has a real importance in the social life of the time."

The modern outlook upon child offences is instinct with the recognition that the state of the child mind has to be considered. It is the putting into daily practice of the dictum of Francis Bacon: "It is the business of the judge to consider, not only the offence, but also the offender." The practice of to-day is well shown in the book on *The Young Delinquent* by Dr Cyril Burt, the psychologist in the Education Department of the London County Council. Its basis is a course of lectures to London teachers, and the book is primarily addressed to schoolmasters, probation officers, and those particularly interested in the care of children. The aim has been to give an exposition of the methods of psychology as applied to this practical purpose, and to make clear the methods of inquiry and the methods of treatment. It is recognized that the subject is too new and experience too recent to admit of final generalizations. There are chapters on the problem and the methods, on hereditary conditions, on environmental conditions, such as the home, companionship, leisure, and work, on physical conditions, as shown in stages of development, and of illness, on intellectual conditions whether subnormal or supernormal, on temperamental conditions, as shown in the

working out of instincts and emotions, habit and neuroses. In each stage the work is carried forward by illustrative cases, in which the facts as first known are stated, then the steps of the inquiry, the final discovery, and the effects of treatment. The book begins with a case which is a parallel to, but far graver than, that cited at the head of this review. Jeremiah Jones, a child of 7½ years, was a thief and a murderer. An illegitimate child of a chance encounter, brought up in a basement room, mentally shaken by a fractured skull at the age of 6, knowing the stigma of his brutality, he took to tinney, petty theft, and in revenge and for covetousness drowned his playmate. The death was supposed to be accidental, but the psychological inquiry elicited the fact that it was purposeful. Then follows, not a sentence of death as in 1735, but the record of the complete investigation of the child's history and character, and the treatment, with the results so far. This is the manner in which each section is treated, and it is comparable to a series of clinical records well taken, amply discussed, with the reasons for treatment and its results displayed. It is to be hoped that this book will have a wide circulation, for it is most instructive.

THE DIAGNOSIS OF ANOPHELINE MOSQUITOS

PROFESSOR STRICKLAND, who holds the chair of medical entomology in the School of Tropical Medicine, Calcutta, has, in his *Short Key to Anopheline Species of India, Ceylon, and Malaya*, produced a work which cannot fail to be of inestimable benefit to the tropical practitioner, who should be conversant with the characters of the chief parasite vectors of the district in which he happens to be stationed. "Running down" a mosquito with the aid of the ordinary dichotomous key is often far from a simple matter, particularly when the specimen is not quite fresh and has suffered in transit. The author shows how, by careful examination of the wing and hind leg, the "spotting" of an anopheline can in a vast majority of instances be accomplished with certainty. Proceeding on these lines he shows the method by which this is done, and gives also confirmatory points which will be of the greatest service to the beginner, helping him to acquire confidence in his own diagnosis. The diagrams are clear and the plates excellently reproduced.

The labour of correlating the various points must have been arduous, since the whole work, though occupying only nineteen pages, is an outstanding example of simplicity, conciseness, and accuracy. If those placed in a similar position in other parts of the world where malaria prevails could be stimulated to follow Professor Strickland's lead the aggregate results would prove a valuable *vade-mecum* for reference.

NOTES ON BOOKS

Four editions in five years are good evidence of the success of Tidy's *Synopsis of Medicine*. As an aid to rapid revision when preparing for the final examination there is probably no book at the present time so much in demand among students in general, and more particularly among those brought up on Osler's *Principles and Practice of Medicine*, whose arrangement it for the most part follows. In preparing the latest edition¹⁰ Dr LETHBRIDGE TIDY has introduced a good deal of new matter, but by judicious use of the pruning knife he has just managed to avoid overstepping page 1000, and we report the hope that in future revisions he will set that number as his upper limit of size. Considerable changes have been made in the chapters on diabetes and jaundice, and other articles wholly or in part rewritten include those on botulism, viscerotoposis, haematoporphyria, infarction of the lung, primary pyuria, rheumatic jaundice, gall stones, bronchial asthma, and splenic anaemia. New matter comprises articles on blood diseases of childhood, and on thrombosis and embolism. The fourth edition of this useful compendium will without doubt maintain its popularity, not merely with the students for whom it is chiefly intended, but also with practitioners who need a trustworthy and comprehensive outline of internal medicine for quick reference in hurried moments.

¹⁰ *A Short Key to Both Series of the Anopheline Species of India, Ceylon, and Malaya*. By C. Strickland, M.A., B.Sc. Camb. Calcutta and Simla. Thacker, Spink and Co. 1925. (Doubtless 8vo pp. 19 illus. 112 rupees.)

¹¹ *A Synopsis of Medicine*. By Henry Lethbridge Tidy, M.A., M.D., F.R.C.P. Fourth edition. Bristol: John Wright and Sons Ltd. London: Simpkin, Marhall, Hamilton, Kent and Co. Ltd. Toronto: The Macmillan Co. of Canada Ltd. 1925. (Cr. 8vo pp. xv + 1000. 21s net.)

London Life in the XVIIIth Century. By Mrs M. Dorothy George. Late Research Scholar of Girton College, London. Kegan Paul, Trench, Trubner and Co. Ltd. 1925. (Pp. 452. 21s net.)

The Young Delinquent. By Cyril Burt, M.A., D.Sc. Oxon. London: University of London Press Ltd. 1925. (Demy 8vo pp. 643. 24s. 6d. net.)

Dr CHRISTIANSEN'S monograph on the *Organic Derivatives of Antimony*,¹¹ one of the scientific and technological monographs issued under the auspices of the American Chemical Society, gives a full account of the many efforts that have been made to treat parasitic diseases with preparations of antimony. In the main the book is written from the chemical point of view, and there are chapters on the aliphatic antimonial preparations, the aromatic stibines and stibinic acids, the antimony compounds, the organic compounds containing triad and pentad antimony, and so forth. In addition there is a chapter by Dr G C Shattuck on the therapeutic use of antimonials, particularly in trypanosomiasis, the leishmanioses, schistosomiasis, inguinal granuloma, and leprosy, no mention of their employment in yaws seems to be made. The volume is clearly written, and should be widely read because it deals with a subject of great and increasing importance.

Professor Dr HANS CURSCHMANN of Rostock, whose text book of neurology was recently reviewed in our columns, has published in a volume a series of clinical lectures on nervous diseases¹² written for the *Munchener medizinische Hochschulschrift*. The lectures cover a wide range of subjects and are written expressly for the guidance of general practitioners. The author's plea is for early diagnosis, as only this can effectual treatment be attained in such diseases as tabes dorsalis, disseminated sclerosis, and spinal tumour. Considering the small size of the volume it contains a remarkable amount of information of an essentially practical sort. The prominent features of the commonest nervous diseases are outlined and diagnostic pitfalls discussed. In addition there are chapters dealing with the differential diagnosis of such outstanding symptoms as neuralgia, headache, and giddiness.

In their *Physical Diagnosis of Diseases of the Chest*¹³ JOSEPH H PRATT and GEORGE E BUSHNELL have produced a work that should be of considerable value to the advanced student and to the general practitioner who wishes to revise his knowledge and improve his methods. The book consists of two parts—the first devoted to the lungs and mediastinum, and the second to the heart and aorta. Like most teachers, the authors assume a low standard of knowledge and a high standard of intelligence in their students. It is not unusual, therefore, to find that they have terted in considerable detail the fundamental principles on which the methods of diagnosis rest. They have insisted too, on an acquaintance with the normal chest before attempting to interpret the more complicated signs of the pathological chest. Though the book is fairly complete, there are some conditions, such as infective endocarditis, that have been summarily dismissed. Their excuse in this instance appears to be that infective endocarditis, though primarily a disease of the heart, is really a septicæmia. This may be so and the authors may naturally determine for themselves what to omit, but it is strange to find that in a book in which 270 pages are assigned to the heart such an important disease should occupy less than two full pages. Apart from a few similar anomalies, the book may be well recommended.

The French original of the late Dr ETIENNE DESTOT'S radiological study of traumatic lesions of the wrist was noticed in our issue of March 15th, 1924 (p 476). We now welcome under the title *Injuries of the Wrist*,¹⁴ the appearance of an English translation by Dr F R B ATKINSON, which was certainly wanted, for Dr Destot's experience in the diagnosis and treatment of carpal injuries must have been unique and an English edition should be of great value to all those who may be called upon to treat them. The French surgeon unfortunately did not live to bring out the book, and the fact that it was prepared and pressed through the press by others may account for some obscurities of language in the original which have evidently taxed the ingenuity of the translator. We could have wished that Dr Atkinson had given us a less literal version and allowed himself more freedom in rendering the text into English, but we must be grateful to him for making a knowledge of Destot's work generally available in this country. The book is well got up, and the reproductions of x-ray plates to which we took some exception in the original, leave nothing to be desired in the translation. As the title implies Dr Destot relied through-

out largely on the evidence afforded by the x-rays, and the translator has rightly translated the subtitle as "A Radiological Study." The interpretation of radiographs of the carpus is by no means simple for the inexperienced, but with this book to guide him the surgeon should escape all the pitfalls which lie in the path of the unwary.

Mr ST GEORGE LANE FOX PITT'S work, *The Purpose of Education*, was first published in 1913, the second edition was noticed in our columns in 1916 (ii, 872). It has now been enlarged and revised and published in a cheap edition.¹⁵ Its object is to provide a clue to the satisfactory solution of educational problems by their psycho-physical consideration, it is highly psychological and not a little controversial. The author insists that to speak of the subconscious mind or self is very misleading, as there is no definite self entity that remains always subconscious, nor any veritable psychic mass, called by the Indians the subconscious, which is invariably fixed somewhere in the personality out of all consciousness. There is much discussion about the use of the term "complex," which the Freudians always employ in a pathological sense, with this the author does not agree. He uses it in a broader sense, following Professor Rhys Davids, who employed it to translate certain philosophical terms in *The Sacred Books of the Buddhists* more than forty years ago. 'Long before Freudianism was ever heard of' Mr Lane Fox Pitt arrives at the conclusion that the only real remedy, as distinguished from temporary palliatives, for pain is such a systematic education as will effectively subordinate our lower to our higher purpose.

The third volume of the transactions of the Association for Research in Nervous and Mental Disease contains the papers and discussions on *Heredity in Nervous and Mental Disease*,¹⁶ which was the subject selected for consideration at the annual congress in 1923. In the editorial preface it is pointed out that this volume is published, not as in any sense a complete investigation of the problem under discussion, but in order to introduce a little intimacy of vision and clarity of thought into the consideration of the question of morbid inheritance by neurologists and psychiatrists. The usual form of publication has been adhered to in this volume, but as it was not found possible to reach any definite conclusions of value none have been published. In spite of the fact that no clear-cut conclusions emerged from the discussions, the book is very suggestive and serves particularly to indicate the directions in which research might profitably be undertaken. It is certainly clear that long and arduous investigations will have to be pursued before we can pretend to understand the causal factors at work in the production of family diseases.

The second part of the first volume of the *Annals of the Pictet Thomson Research Laboratory*, a publication designed to aid the working bacteriologist by giving him a series of photographs and microphotographs illustrating the growth of pathogenic and other bacteria, contains five papers. These deal with certain nutrient media, *Bacterium pneumonitidis*, of the respiratory tract, the classification by microphotography and the germs and tissues there are photographic and microphoto-

graphic plates.

Mr G E JORGENSEN'S book on *Veterinary Diagnosis and Treatment*¹⁷ may be described as a voluminous case book in which the author has collected some 130 cases of sickness in horses, cows, swine, sheep, dogs, and cats, and set them out in eight chapters in accordance with the system mutually affected. The history, diagnosis and treatment are given in each case, together with an account of the *post mortem* appearances in many instances and a discussion of the completed case as a whole. There is an inadequate index, and the search for information on any particular point in the pages of the book is not easy owing to the way in which it is arranged. Still, its perusal leaves the reader with a good deal of unclassified veterinary knowledge in general, and it may be recommended to the attention of practising veterinary surgeons. It contains many errors in spelling.

THE LONDON SKULL

BY

G THOMAS SMITH, M.D., Litt D., D.Sc., F.R.C.P., F.R.S.,
PROFESSOR OF ANATOMY, UNIVERSITY COLLEGE LONDON

It is just a century since Charles Lamb was pensioned and left East India House in Leadenhall Street and the place where the gentle Eli, in the intervals of his clerical labours, conceived his imperishable essays is now occupied by a vast excavation, 50 feet deep in which the new building for Lloyd's is being erected. For 14 feet below the present level of the street remains of the former Roman occupation are visible, lower down 12 feet of undisturbed "dirt" rest upon 14 feet of river gravel below which (that is, 40 feet below the street level) is the blue clay. Last March the ulna of a woolly rhinoceros (*Rh. antiquitatis*) was found in the blue clay, in which a human skull has recently been found. There can therefore be no doubt of the remote antiquity of the original owner of the skull, who was a contemporary of the woolly rhinoceros and the mammoth in what is now the heart of the City of London. But as the Flood Terrace of the Thames, in which it was found, is supposed not to have been deposited until after the disappearance of Neanderthal man from Europe, this is presumptive evidence that the fossil is unlikely to belong to the extinct species (*Neanderthalensis*), and that it cannot be earlier than the Aurignean period. This skull of the Upper Palaeolithic period, however, represents the earliest human remains yet revealed in the City of London.

The fragment (Fig. 1) includes most of the occipital and left parietal bones, and part of the right parietal. The position of the groove for the middle meningeal vein (Fig. 3, B) indicates that the point of bone in front of it reaches to within a millimetre of the coronal suture. The closing of such parts of the sagittal suture as are represented in the fossil and of the lambdoid suture (excepting its lowermost part (Fig. 1) and the endocranial suture in the neighbourhood of the lambda (Fig. 2)) suggests an age of between 40 and 50 years. The exceptional smoothness of the skull and the faintness of the muscular impressions in a person of middle

age indicate the probability that the sex was female. The reasons for claiming that "the lady of Lloyd's" was left-handed are discussed in a later paragraph.

The rough sketch (Fig. 1) indicates the exceptional flatness (compare its height with that of a modern woman M)

and distinctive outline of the cranium in the median line. The profile of the cerebral hemisphere (indicated by the broken line) is identical in size and shape with those of the two women of the Neanderthal species, but the flattening of the cerebellum in the latter (see the lines of the Neanderthal cerebellum and occiput at N) in comparison with its fullness in the London fossil marks the completeness of the resemblance to the Neanderthal type.

But the likeness of the cerebral part of the endocranial cast in the London and Neanderthal women involves not only the contour of the outline but also the modelling of the surface. In the endocranial casts of *Pithecanthropus*, the Piltown skull, and the Neanderthal women (La Quina and Gibraltar crania) there is a prominent boss in the region of the posterior part of the middle temporal convolution, corresponding to the area so intimately concerned in modern man with the acoustic symbolism of speech. In modern man the expansion of the surrounding cortical areas raises them to the level of this pre-cerebrally developed eminence so that the boss is no longer

apparent. In the east of the London skull the temporal eminence (Fig. 3, T) is still present, and the parietal area (P) above it almost as flattened as it is in the Neanderthal crania. In fact, there is a striking resemblance

to the configuration of the La Quina east. The maximal breadth of the intracranial east is intermediate (136 mm.) between the measurements of the La Quina (130) and the Gibraltar crania (140). It is obviously impossible to measure the cranial capacity from this fragment but by comparison with the Gibraltar skull (itself imperfect) one can safely say that the cubic content of the London cranium cannot have exceeded 1,200 c.c. by more than 50 c.c. at the most.

Although most of the crania of Upper Palaeolithic man are flatter than those of the average modern man their height approaches more nearly to the latter (Fig. 1,

M) than to that of the London skull which in this respect agrees with the Neanderthal standard. In other words, the London skull more nearly resembles the Neanderthal type than any other of the Upper Palaeolithic specimens does. The likeness is so real as to raise for serious con-

FIG. 1.—Tracing of the median contour of the London skull (thick line) contrasted with the corresponding part of a modern British woman's skull (M). The dotted lines at N reveal the only difference of the contour of a Neanderthal woman's (La Quina) skull, the cerebellum being much flatter and the occiput adapted to the altered form.

FIG. 2.—Drawing by Mr. A. H. Maxwell of the interior of the London skull viewed from in front. L, cribra lunata; F, foramen ciliare; S, the small foramen ciliare of the left side.

sideration the possibility whether in Britain a stray member of the Neanderthal species may not have survived after the Mousterian phase of culture had been superseded by the Aurignacian.

Apart from the age of the fossil (that is, its deposition in beds later than that associated with Neanderthal man), the form of the cerebellum and its bony receptacle (Fig 1), the thinness of the cranium, and the slightly greater fullness of the parietal area suggest that "the left-handed lady of Lloyd's" was an exceptionally primitive member of the species *sapiens* rather than a belated Neanderthaloid. Though the London cranium is no thinner than the Ta Qina specimen, this is exceptional for a member of the Neanderthal series. Hence it must be given due weight as a reason for excluding the Londoner from the latter species.

Without the front of the cranium or the face it is not possible definitely to exclude the possibility that this skull may belong to the Neanderthal species, but I think the probabilities are against such a conclusion, both on anatomical and geological grounds. This uncertainty does not diminish the interest of the London skull, for the enigma of its affinities emphasises how closely a primitive type of *Homo sapiens* may approach the Neanderthal species.

Reference has already been made to the probability that "the lady of Lloyd's" was left-handed. Some explanation will be demanded in justification of a claim so confidently made.

Twenty years ago, when investigating the occurrence of the so-called Affenspalte (sulcus lunatus) in the human brain, I called attention to the fact that it was often found as a large semilunar furrow on the left hemisphere (Fig 4), but much on the right. Moreover, I recorded the observation that the cortical territory, for which I coined the term "area striata" was often raised into a prominence behind the sulcus lunatus (as in the Egyptian brain shown in Fig 4). Corresponding to this prominence there is often a deep depression on the left side of the occipital bone (fossa corticis striatae) surrounded by a ridge (crista lunata) corresponding to the sulcus lunatus. In the winter of 1907-08 Professor F. Wood

Jones collaborated with me in the attempt to discover the significance of the occasional reversal of the asymmetry usually found in the cerebral hemispheres. In his field notes on the skeletons found in the course of the archaeological survey of Nubia he recorded whether the right

or the left humerus was the longer, and on this basis inferred, in the case of each skeleton, whether the individual was right-handed or left-handed. Using these data I discovered that when the deep fossa striatae and the extensive crista lunata were on the right side, and not on the left, it afforded a reliable criterion of left-handedness. The London skull affords an excellent illustration of this

phenomenon (Fig 2). On the right side (left of the figure) there is a prominent and extensive crista (L) and a deep fossa striata (F), whereas upon the left hemisphere there is only a very diminutive fossa (S). This is a reversal of the customary arrangement (seen in Fig 4), and, I believe, affords definite evidence that the earliest known Londoner was left-handed.

In my earlier memoir on the asymmetry of brain and skull (op cit, 1907) I laid undue emphasis on the arrangement of the venous sinuses, when I suggested that the common deflection of the superior longitudinal sinus into the right lateral sinus was usually related to the slighter backward projection of the right hemisphere. In fact I assumed that this arrangement of the largest venous channel was determined by purely mechanical factors, the asymmetrical condition of the occipital poles allowing more room for the blood to flow freely to the right. This tentative explanation may still have some measure of justification. But it is evident—as the condition revealed in the London fossil indicates—that other factors must play

a part in determining the asymmetry of the cerebral sinuses, and that the reversal of their normal asymmetry is not necessarily in indication of left-handedness. Although the deflection of the superior longitudinal sinus into the left lateral sinus is usually associated with left-handedness the correlation is not invariable. In the London skull, for example, the groove for the superior longitudinal sinus splits at the torcular herophili into two lateral sinuses of almost equal size (Fig 2), as is usual in the apes, but of the two the right is slightly larger than the left. Thus, while the brain conforms to the condition distinctive of left-handedness, the right lateral sinus is larger than the left, as is usual in right-handed persons. When the evidence of

asymmetry is thus conflicting, examination of a series of crania (and the arm bones of the skeletons) reveals that the brain and not the venous sinuses is the real index of right- or left-handedness.

I have to express my gratitude to Mr. Warren R. Dawson for calling my attention to the interesting fossil discussed in these notes and to the Committee of Lloyd's for its generosity in presenting it to University College.

FIG 4—Anterior aspect of an Egyptian brain viewed obliquely from the left side to show on the left hemisphere but not on the right the large sulcus lunatus and prominent button of area striata behind it (compare Fig 2).

The question of the cranial signs of right and left handedness were discussed more fully in a paper read in the Section of Anatomy at the Annual Meeting of the British Medical Association in 1908. An abstract of the paper was published in the *Journal* of August 29th 1908.

British Medical Journal.

SATURDAY, NOVEMBER 7TH, 1925

RADIOLOGY AND RADIOGRAPHY

MEDICAL radiology, speaking broadly, depends on two factors for a diagnosis: production of a radiogram and correct interpretation. To arrive at the latter the clinical side, as a rule, has to be taken into consideration, and consequently medical training is required. Two different kinds of ability are therefore necessary, and the possession of one by no means implies endowment with the other. Even if it is admitted that an expert lay radiographer may occasionally be equal to or even excel a medical radiologist in the matter of skill in the production of a radiogram, the layman cannot possess the knowledge the medical specialist has of the physiological and pathological conditions of the parts displayed. To draw such a distinction is not to cast any reflection on the radiographer, whose skilful technique may be very valuable in assisting a diagnosis. Credit is due to the radiographer, who for many years, at considerable personal risk, has perfected himself in his technique. But though during this time he may have gained useful knowledge of the conditions seen in health and disease, it does not entitle him to usurp the responsibility of the medically trained radiologist in making a diagnosis. Such a distinction is not peculiar to radiology. The preparation for microscopic examination of a fragment of uterine tissue, and the responsibility of diagnosing from its appearance the existence of chorion epithelioma is a parallel case. Again, a layman with the requisite chemical training can detect the presence of sugar in the urine, but the diagnosis of diabetes demands expert medical consideration. A deep knowledge of the pharmacology of digitalis does not entitle a chemist to diagnose and treat auricular fibrillation. Such examples could be multiplied, and careful examination of the diagnostic and also of the therapeutic functions of radiology shows that such a distinction is of vital importance.

The problem presented to the general practitioner is twofold: there is the clinical side and the ethical side. The radiological diagnosis of a fractured bone presents no difficulty as a general rule, and such difficulties as occur can usually be overcome by refinements of technique. Were radiology limited to such simple problems the question of medical as contrasted with radiographical skill would hardly arise. But this is not the case. The chest affords a very large field for both radiography and radiology, and there are few who would dare to claim that the last refinement of skill has been obtained by the most expert technician or diagnostician. For example, using radiography alone, the differential diagnosis between pulmonary tuberculosis, primary malignant disease of the lung, and pulmonary syphilis is still difficult, and depends on clinical considerations of a varied nature. Again, there is more than one possible cause for enlarged bronchial glands, though the appearances presented by the radiograms in each case may be almost indistinguishable. Primary malignant disease of a bronchus is yet another difficult diagnostic problem, while pericardial effusion may easily be overlooked in a radiological examination by one who does not possess

clinical knowledge. The distinction between early periosteal sarcoma and myositis ossificans is slight and very subtle, yet the life of the patient may depend on the right answer being given. In all these difficulties the discoveries of physiological and pathological research must be taken into account, or the diagnosis will be little more than a gamble, with consequent grave risk of faulty treatment and inaccurate prognosis, the welfare of the patient may be endangered and a professional reputation threatened. It has before now proved impossible, even after the most careful radiographic examination, to distinguish between renal calculi and calcareous mesenteric glands, until the application of pathology pointed to a conclusion subsequently confirmed by surgical operation. In such a case the most skilful interpretation of the findings by a radiographer is inadequate until reinforced by the wisdom derived from long study of pathology. Here also is raised the very important point that the medical radiologist must not be a specialist in a narrow groove; he must possess a full knowledge of the anatomy, physiology, and pathology of the regions under examination. He assumes a heavy responsibility in making a diagnosis, and a high degree of preliminary medical training must be his. The responsibility is no lighter in the case of a general practitioner called upon to interpret a radiogram, and it is not too much to say that the progress of radiology has been definitely impeded by the failure of some to recognize the difficulties of such diagnosis. To entrust this responsibility to those who have not had the general and special training the medical student receives in his ordinary education is therefore, indefensible. This is admitted by many lay radiographers, whose status is not thereby lowered. In therapeutics also the use of x-rays entails a heavy medical responsibility, and the treatment of each patient requires the careful supervision of one who has been specially trained to detect the early manifestations of disease and to appreciate the slight, and sometimes conflicting, evidences of improvement. With such dangers to be remembered, both in diagnosis and in treatment, the position of a hospital or infirmary which is content to dispense with a consulting medical radiologist on its staff is most unenviable, and yet, though medically trained pathologists and ophthalmologists are admittedly essential members of a hospital staff, the consulting radiologist is still too often considered an unnecessary luxury. While large sums of money are being devoted to the perfecting of apparatus in medical institutions, yet in some the clinical interpretation is left in unskilled hands, and patients are thus exposed to considerable risks. Such a state of affairs is deeply to be regretted.

The welfare of the patient is the primary ethical consideration. Now it is generally recognized that in the interests of the patient the functions of diagnosis and treatment must be limited to those who have received a medical education and are subject to the jurisdiction of the General Medical Council. Medical practitioners are prohibited from associating with unqualified persons who may assume medical functions, but the General Medical Council has no other power of restraining the unauthorized activities of lay diagnosticians and healers. It is therefore incumbent on medical practitioners, in the interests of their patients as well as for their own professional security, to see that the line between radiographers and radiologists is honourably observed. It is not sufficient to rest upon the admitted fact that the vast majority of radiographers, clearly recognizing their obligations and

interests, are as scrupulous in their behaviour in this respect as they are eminent in the value of their services to the medical profession and to humanity. Exceptions do, unfortunately exist, and are tolerated, not only by individual practitioners, but also by authorities of institutions who might be expected to take wider views. There is no shortage of medically trained radiologists, but there is a sad lack of hospital appointments for them. This is not the case in America and on the Continent where the holding of radiological posts in public institutions by non-medical radiographers is almost unknown. Both radiographers and radiologists have much to gain from the termination of the present confusion between them. The efforts of the Society of Radiographers in this direction, together with the influence of the British Institute of Radiology, need only the co-operation of general practitioners and of hospital authorities to bring about great advances in radiology, which has owed so much in the past to the unselfish co-operation between radiologists and radiographers.

THE MELANOMATA.

THE pigmented tumours, or melanomata, have in recent years commanded much attention from pathologists, the reason being that they afford special facilities for the study of the histological processes of malignant disease. Mr W. G. Spencer took a wide view of melanosis in his Bradshaw Lecture to the Royal College of Surgeons of England two years ago,¹ and now the *Edinburgh Medical Journal* has devoted the whole of its fasciculus for October to an essay on the melanomata by Dr James W. Dawson, histologist at the Royal College of Physicians Laboratory, Edinburgh. The subtitle of Dr Dawson's paper is "A study of cell origins and transformations, with a critical discussion on aspects of tumour growth," and this justifies the statement that the real interest of an investigation into the morphology and histogenesis of the melanomata lies in the light that they can be made to throw on tumour growth in general. The research appears to have been undertaken primarily with the object of throwing light on the variations in form which are not infrequently met with in the cells of malignant growths and at times render diagnosis difficult. For such a study the melanomata are peculiarly suited, owing to the extreme variability of their histological structure. The research has led Dr Dawson into an exhaustive investigation, both clinical and pathological, of the entire group of melanomata, innocent and malignant, and the result is a volume of some two hundred pages which practically constitutes a textbook of these tumours, and will, there can be little doubt, take its place as the standard work on the subject.

To the pathological histologist, who on such a matter as this must be the guide of the practitioner, the centre of interest in a new work on melanotic tumours will be the discussion on the nature of the so-called melanotic sarcomata. There are probably few pathologists who feel on firm ground in making use of that term. It is time honoured and convenient, since there is no mistaking what growth is denoted by it, it may represent the truth, but of this there is no proof. In many cases the growth has the apparently unmistakable histological characters of a sarcoma, but it may take the form of an endothelioma, and, moreover, from several important features in its clinical course and mode of dissemination, it is difficult to avoid the

conviction that it is a carcinoma. The author has fairly faced this complicated problem, and after an exhaustive histological study has reached the definite conclusion that the growths are, in all cases, of epithelial origin—that is to say, are carcinomata. There seems to be a general consensus of opinion among pathologists that these tumours arise from certain pigmented cells occupying the deeper layers of the epithelium, and from the so-called naevus cells of the corium, but with regard to the nature of both of these groups of cells there is a divergence of views. According to the observations of Ribbert there exist in the basal layer of epithelium a number of intercalated cells of connective tissue type which act as melanoblasts or producers of melanin. These are considered to have migrated from the corium, and if this view be correct the tumours arising from them are properly spoken of as sarcomata. In the same way, if naevus cells are regarded as modified mesodermal cells, the name melanotic sarcoma is appropriate. There is, further, the theory of Kromayer, that naevus cells are epithelial cells which have migrated into the corium and have become converted into true connective tissue cells, as evidenced by the existence of an intercellular substance, regarded by him as a product of the cells. Tumours arising from the latter would be rightly classed as sarcomata.

With regard to Ribbert's view, Dr Dawson finds, from an investigation directed especially to this point, that there is no evidence of any migration of cells towards the epithelium, and he considers that naevus cells are derived from the basal epithelium by migration into the corium. He bases this conclusion on a comparison of pigmented moles of gradually increasing complexity. In the simplest form there is found merely a localized pigmentation of the deeper cells of the Malpighian layer, with a few phagocytic and pigmented connective tissue cells in the papillae. In a later stage groups of basal cells become loosened from one another and assume a branched or spindle form, these break away from their epithelial connections and are found lying in the connective tissue of the papillae. In the final stage columns of small polymorphous cells (true naevus cells) are found in the corium, together with branched pigmented phagocytic connective tissue cells. No definite connexion could be traced between the cell columns and the basal epithelium, but the impression received from a study of the sections was that of a process advancing from the surface inwards rather than in the opposite direction. With regard to Kromayer's theory, the author admits that, although it implies a violation of the laws of histogenesis, which hold to the specificity of the germinal layers, it cannot be lightly dismissed. He considers, however, that the intercellular substance which separates the tumour cells and suggests their connective tissue nature consists merely of the disassociated connective tissue fibrils of the corium.

Dr Dawson traces in detail the stages in the formation of the melanotic growths from the basal epithelium, making a distinction regarding their point of origin—whether it be in the interpapillary processes or in the bridge of epithelium uniting these over the summits of the papillae. Tumours of the alveolar type appear to take origin in the latter, while those developing in the interpapillary processes tend to assume the form of sarcoma. In either case the earliest change is similar to that seen in the development of naevus cells, groups of basal cells are found loosened from their neighbours and assuming branched and spindle forms, proliferation then occurs, with

¹ BRITISH MEDICAL JOURNAL, 1923, vol. II, p. 907.

penetration into the corium. In those cases in which the primary change is in the interpapillary process, the proliferation leads to enlargement of the process, so that it is compressed between the adjacent papillae, its cells become flattened and spindle shaped, and in penetrating between the connective tissue fibrils of the corium produce the appearance of a spindle cell sarcoma.

From the many excellent illustrations in Dr Dawson's paper his contention that these tumours are of epithelial origin appears to be fully borne out. It involves, however, the assumption that the basal epithelial cells are true melanoblasts, and, further, calls for some explanation of the change from the epithelial to the branched form of cell in the early stages of the process. The latter point is sufficiently accounted for according to the author, by the increased activity of the cells, and with regard to the pigmentary function of the epithelium he is supported by the researches of Bloch, who has shown that pigment producing cells function by means of a ferment (oxidase) which is specific to them, and that the pigment is formed from a chromogenic substance which the cells absorb from the surrounding tissue fluids. He claims that it is possible to distinguish melanoblasts from other cells by bringing the ferment into action. This is done by supplying the cells with dihydroxyphenylalanine (a term happily abbreviated to "dopa"), a substance which acts as a substitute for the normal chromogen and forms pigment under the action of the ferment. By this test it may be shown that the whole of the basal epithelium is "dopa positive," whereas mesenchymal cells, including the branched pigmented connective tissue cells of the corium—the chromatophores or carriers of pigment—are "dopa negative." It is claimed that the production of pigment is proved by this reaction to be a specific function of the epidermis and its derivatives. With regard to melanomata arising in the eye, the central nervous system, or other internal organs, the author shows that there is good reason to suppose that they are derived from melanoblasts that have migrated from epithelium in a manner analogous to the migration of nevus cells.

MEDICAL RESEARCH IN SOUTH AFRICA

In the annual report for 1924 of the South African Institute for Medical Research, the director, Dr W. Witwaters-Pitchford, describes the rapid increase in the work of the institute, which is now on a very large scale. The financial value of the institute, apart from the land (which was granted by the Government of the Union of South Africa), is now nearly £120,000, including an endowment fund of just under £50,000. Additional income received during the last year from the Union Government and from the Witwaters and Native Labour Association has rendered it possible to organize and staff departments of medical entomology and biochemistry, to extend the bacteriological research department, and to erect additional laboratories and other buildings. Difficulty was experienced in attracting research workers from the large European centres, but the hope is expressed that graduates of the South African universities will come forward in increasing numbers to fill the vacancies that exist. An advisory committee, including medical representatives of the institute, the Union Department of Public Health, and the Witwaters and Native Labour Association, has been formed to co-operate in promoting research and improving public health administration. The research work during the year has included the isolation of suitable strains of the meningococcus and

the pneumococcus for the preparation of antimeningococcal serum and pneumococcal vaccine, and some aberrant types of pneumococci have been detected. Indications have been found that minute foci of infective silicosis are commonly present in the lungs of miners without giving rise to any recognizable signs or symptoms. Undulant fever, schistosomiasis, and the relation of persistent pulmonary lesions to tuberculosis, are other subjects that have received special attention during the year.

PREHISTORIC TREPHINING

Among the various abnormal marks and defects met with in the skulls of prehistoric races the most interesting are those which are unmistakably due to surgical operation, more especially to the operation of trephining. Many fanciful theories have been advanced to account for the origin of this operation among primitive peoples. For instance, it has been suggested "that the custom of trephining wounded captives would almost necessarily grow up, with the idea that a mystical significance attached to the operation as a sort of ordeal." Dr D. J. Wolfel of Vienna, relying less on imagination than on a careful examination of the cultural features of races, has advanced a more probable, if more prosaic, explanation of the practice. He has endeavoured to trace an organic connexion between the practice of trephining and some definite cultural feature of the primitive civilizations in which the operation exists. He points out that the method hitherto adopted in studying this subject, by which observation is confined to a single area, is apt to prove fallacious, since it is impossible by this means to disentangle merely accidental from organic relations. It is only by comparing different civilizations practising trephining that a true organic connexion is likely to be discerned. Since the prehistoric races afford insufficient material for such a comparison, Dr Wolfel has sought a solution of the problem in the primitive and half-civilized races living at the present time. The operation of trephining is known to be employed by the Beibers, the Abyssinians, and until recently by the Albanians and Serbs, passing eastwards there is a wide gap, the operation reappearing extensively in Melanesia and New Guinea and again, to a still greater extent, in America around the sources and banks of the Mississippi, throughout Mexico, and, with a large gap in Central America, southwards as far as Chile. Dr Wolfel has examined the cultural conditions in two of these regions, Melanesia and South America, and has sought for some cultural feature that is constantly associated with the practice of trephining and present in both areas. As regards Melanesia he finds that the operation is intimately related to the use of certain weapons—namely, the sling, the wooden club, and the stone-headed club. Trephining is not found in regions where the sling is not used. The trephine area is not quite co-extensive with the sling area, but this is, in Dr Wolfel's opinion, probably due to variations in the type of sling employed. The areas in which the club is used are in all cases within the trephine area. In totemistic districts on the other hand, where pointed and therefore more immediately deadly weapons are employed, inflicting wounds for which trephining would be useless, the operation has not been introduced. Precisely similar relations are found to exist in South America as in Melanesia, and Dr Wolfel concludes that it is reasonable to suppose that trephining was introduced at the same time as the sling and club, and is to be regarded as belonging to that level of civilization of which these weapons form a feature. He gives a very interesting account of the operation itself, which appears to be frequently employed not only for head injuries, but also for affections in which cerebral symptoms are a prominent feature, such as headache, epilepsy, and diseases

associated with loss of consciousness. In many of these cases the operation takes the form of a linear osteotomy rather than trephining, and, so far as indications are concerned, seems to correspond to our modern operation of decompression. It is also noteworthy that a similar operation is frequently performed on children as a prophylactic against subsequent cerebral disorders. In these cases the operation is performed by the mothers, with an almost negligible immediate mortality.

RECORDS OF TEMPERATURE AND PULSE

In a lecture at the James Mackenzie Institute for Clinical Research, St Andrews, on October 20th, Professor Patrick described some observations on temperature and pulse rate, and showed an interesting series of charts illustrative of most of the common fevers. He strongly advocated greater accuracy in recording temperature, drawing attention to the common practice of nurses of omitting to record temperatures below 97° F. Similar inaccuracy was common in regard to high pulse rates. The physician, wherever possible, should check the records by his own observations. Professor Patrick insisted on the extreme value of graphic records of the pulse rate, a gradual rise in rate being more readily detected where this method is employed. In rheumatic fever, for example, a pulse chart is the best indicator of the onset of endocarditis. He deprecated the use of the word "normal" in relation to a fixed point of temperature such as 98.4° F. This might be regarded as the upper limit of normal temperature, but in nearly all healthy individuals the average morning temperature was considerably lower. As a rule the pulse rate increased about ten beats as the temperature rose one degree, but there were wide differences in this ratio in different diseases. He drew attention to the fact that in many febrile conditions the quickened pulse of fever was succeeded during convalescence by an unusually slow rate. He considered that all these matters required more accurate recording and fuller investigation.

SPIRITUAL HEALING IN BRADFORD

RATHER more than a year ago considerable interest was taken by the newspaper press in a spiritual healing mission held by Mr. J. M. Hickson at Bradford. The mission appears to have had the approval of the Bishop of Bradford. Dr. Perowne, and was held in the Farringham Parish Church, of which the Rev. J. H. Warner is vicar. On October 15th last an anniversary healing service was held at the same church, and Mr. Hickson was present. The Bishop of Bradford had been expected to attend the service, but sent apologies for his absence. On this occasion newspaper representatives were excluded, the explanation given was that the bishops did not wish such services to generate excitement, or (as the Bishop of Bradford told an interviewer) that the service should be made into a "stunt." Mr. Hickson and the vicar both allowed themselves to be interviewed after the service. The vicar thought that most of the bishops were watching the movement with a certain amount of sympathy, while Mr. Hickson remarked that there had been a marked change in the medical world towards the work of spiritual healing. He said that he had received an invitation to address the students of a large medical university "not very far from Bradford," and that he was also going to give the first address on spiritual healing in a London hospital. It does not appear, however, that either Mr. Hickson or Mr. Warner was very illuminating on the results of the year's work. There is a statement that the vicar recently visited a woman who, a year ago, created something of a sensation by discarding one of her crutches at the church door, and that he found her "bubbling over

with thankfulness." On such a case the only suitable comment is the remark of Dr. Morris Fishbein in his book *The Medical Lollies* (to which we lately referred in an article on osteopathy and chiropractic) that "the healing of the crippled, particularly those who cannot walk because of rheumatism, is regularly accomplished and cited to the point of monotony by all of the variegated forms of faith healing." A letter was quoted by the vicar which he had received from a Mrs. Alday, of Tong, Bradford. A year ago she was bedridden, and reported by the doctors to be "a hopeless case." She wrote that since receiving Mr. Hickson's ministrations she had been able to do housework for a family of seven, and was free from pain. Unfortunately the press reports do not give any diagnosis of the condition in either of these patients. Mr. Hickson produced a series of photographs of a New Zealand woman with a deformed leg. The series showed the improvement which had taken place since the woman had attended one of Mr. Hickson's spiritual healing services in New Zealand. As the reporter does not seem to have diagnosed the disease from the photographs, we are left in doubt how far the *post hoc* was *propter hoc*. Further information would be useful also in the case of the man who, with the most powerful glasses, was unable to read large figures on the price tickets in a shop. After the mission he appears to have gone back to the same shop to look at the price tickets, and to have been amazed to find that he could read them without glasses. In such a story it seems almost a pity that the nature of the goods to which the price tickets were attached is not mentioned; this would have added to the interest. But the cure above all cures did not occur, unfortunately, at Bradford. A man who attended one of Mr. Hickson's missions in Canada in 1919 had since developed diabetes. He travelled 6,000 miles to London for the purpose of receiving the "laying-on of hands" for this disease, and he had left for home saying that he "felt all right."

THE MOSQUITO MENACE IN ENGLAND

DURING the late summer the question of bites by mosquitos and other insects assumed in some parts of the country a position of considerable importance. Blood-sucking flies and midges, which the laity class generically under the term "mosquitos," were in some health resorts—not only on the coast but in inland districts also—so persistent as to interfere with the comfort of holiday makers, and, in individual instances, either from inoculation of virus at the time, or from introduction of infection subsequently by scratching, even fatal results were recorded. In short, the menace acquired such proportions that preventive measures were demanded. Prior to 1917, with the exception of the Fens, Haring Island, and a few isolated areas whereague or marsh fever was known to prevail, the majority of persons, medical as well as lay, were inclined to regard malaria and mosquitos as more or less confined to the tropics. The return of infected soldiers from abroad led to the formation of foci of malaria, and the presence of the vectors of the parasite resulted in fresh cases being locally contracted. Although there is no longer any appreciable danger of transmission of malaria, introduced cases being relatively very few, the mosquito menace nevertheless remains, and investigations have shown that there are at least twenty-six different species in England. If the same measures of control would suffice for all this would be no great matter, but the case is far otherwise. Some species are best attacked in the larval stages, others in the adult, some prefer to breed in brackish water, others in fresh, others, again, in refuse, some can be controlled by prompt removal and destruction of garbage, others need careful supervision of areas of stagnant water, paraffining of water-butts, and so forth. A pamphlet written by Mr. F. W. Edwards and Lieut-Colonel S. P. James jointly, and issued recently by the

Trustees of the British Museum (Natural History) is a mine of information on the subject, the authors point out not only which of the various species are noxious and which harmless, but also how they may be distinguished, what parts of the country they frequent, and the ways in which they may be held in check. Since the various species differ greatly in their habits and habitat, their seasons of prevalence, their breeding sites, to name only a few of their characteristics it is essential, in order that measures of control may be undertaken on rational lines with any prospect of success, to identify the species infesting any particular locality, otherwise we shall have learnt nothing from our tropical experiences where expensive schemes for the control of mosquito-borne diseases have been rendered fruitless owing to the failure to recognize the important fact—*auties moustiques, auties mours*. The value of pamphlets written in language readily understood and dealing not with speculations but ascertained facts, and issued thus authoritatively, is inestimable.

FUNCTIONAL DISEASES OF APPLES

Two years ago an interesting inquiry into the functional disease of apples known as "brown heart" was published by the Food Investigation Board. Dr Franklin Kidd and Dr Cyril West, who conducted the inquiry, extended their investigations and published a further report on functional diseases of apples last year in the *International Review of the Science and Practice of Agriculture*. The Food Investigation Board has now brought their report up to date, and has published it for the benefit of readers who are not likely to have access to the international bulletins. The new conditions with which the report deals are the diseases known as "apple scald," "internal breakdown," and "frost injury," in addition to "brown heart". These are all caused by cold storage, and are due generally to causes affecting the apples both before and after storage. They are types of physiological or functional disease (as distinct from fungal rot) which have been recognized concurrently with the adoption of refrigeration, and are causing serious losses. They possess one character in common—namely, premature browning of the whole or part of the tissues of the fruit, but an identical appearance and distribution of the browning may be due to widely different causes. Apple scald, which is a browning of the skin only, is more liable to affect apples placed in storage before they are mature, and is best prevented by storing at a low temperature of 32° to 34° F., and the use of wrappers impregnated with odourless mineral oil, or by the distribution amongst the apples of oiled straw or shredded oiled paper. Internal breakdown, on the other hand, is more liable to affect over-ripe apples or apples grown in cold damp climates, although in rich soils, than those grown in dry warm climates and light sandy soils. In storage the lower temperature of 32° to 34° F. is more likely to cause this breakdown of the tissue than a somewhat higher temperature. Brown heart, as the original report showed, is due to concentration of carbon dioxide above a certain limit, oxygen being present, in the storage atmosphere. Frost injury may be slight, moderate, or severe, and with or without surface disfigurement. It is indicated by meakness in thawing in the slightest cases, and in the severe cases by waterlogging and translucency of the tissue. The condition is caused by the formation of ice in the tissue, and an interesting point is that bruising by blows or pressure after the fruit is frozen results in severe frost injury, whereas little or no injury arises from bruises previous to freezing. The most

disconcerting feature of these functional diseases, so far as the consumer is concerned, is that an apple may appear on the surface perfectly sound, and its diseased condition be discovered only after it is cut.

THE HOWARD KELLY COLLECTION OF THE HIPPOCRATIC CORPUS

THE Johns Hopkins Hospital has, as a result of the late Sir William Osler's stimulating influence, long been enthusiastic in medical history, and his colleague Professor Howard Kelly has fostered this form of culture by the presentation of his collection of the works of Hippocrates and Galen. On this gift Dr John R. Oliver has written a grateful medico-historical note. While mentioning with appreciation the labours of Dr W. H. S. Jones and his recent *The Doctor's Oath*, he agrees that, unlike so many other parts of the domain of classical philology which have been explored inch by inch by countless generations of scholars, the realm of Hippocratic research is almost virgin soil, and that an enormous amount of spadework remains to be done. Dr Oliver touches on some of the outstanding problems which appeal to the Hippocratic student, not the least of these is that this wonderful personality, who dominated medicine from the fourth century before Christ until less than a hundred years ago, is practically unknown to us. Among the works—some sixty or so—making up the Hippocratic Corpus five or six would appear to have the hall-mark of the clear-thinking, broad-visioned mind that we would imagine to have characterized the Father of Medicine, but hardly one of them has not at one time or another been rejected by scholars and editors as unauthentic. The Corpus Hippocraticum is a wonderful collection, for there is hardly any branch of modern medicine that it does not touch at some point or other, and it obviously cannot, any more than our twentieth century "systems," be the work of one man. In another article² Dr Oliver remarks that the book on "the sacred disease" (epilepsy) contains much in the way of acute psycho-pathological observation, which, though forgotten in the Middle Ages, has a strangely modern sound. The first printed Hippocratic work appeared in 1525 in Rome as a Latin translation of inferior quality by Calvus, it is one of the rarest of all the editions, and the Howard Kelly collection is fortunate in possessing a copy. The contents of this collection provide Dr Oliver with an opportunity, which we welcome, of giving an interesting bibliographical summary of the editions down to 1806, he also refers to some later ones, among them to Francis Adams's *Genuine Works of Hippocrates* (1849) in the Sydenham Society's collection. His description of Francis Adams of Banchory as "a London physician" will make Londoners wish that this honour had been metropolitan rather than Aberdonian.

THE PREVENTION OF DIPHTHERIA

In reviewing the annual report for 1924-25 of the Metropolitan Asylums Board (September 26th p. 579) reference was made to certain paragraphs in it calling attention to the increase of diphtheria in London during the past fifteen years. It was pointed out that as the incidence of diphtheria among children under 10 years of age is about two thirds of the total, the likelihood of a child under that age becoming infected with the disease is now approximately twice as great as it was in the period immediately prior to 1911. The Board considered these figures a powerful argument for the adoption of some form of immunization in an attempt to stamp out the disease, and pointed out that the recent statistics for New York City showed a marked decline in the incidence of diphtheria, which it seemed reasonable to conclude was due, in part at

¹ Sold at the British Museum (Natural History), Cromwell Road, N.W., and by B. Quaritch Ltd., Dulau and Co. Ltd., the Oxford University Press, and Wheldon and Weir Ltd., London, and by Oliver and Boyd, Edinburgh. 1925. (Extra pp. 810 pp. 27 4 figures. Price 6d net.)
² *Functional Diseases of Apples in Cold Storage*. By Franklin Kidd and Cyril West. D.S.C. Food Investigation Board Special Report No. 25. London: H.M. Stationery Office, 1925. (810 pp. vi + 15 1 figure in text, 2 tables and 19 figures in 13 plates.)

least, to the immunization measures adopted there, during the past few years over 500 000 school children had been tested, and about 125,000 of these were found susceptible and had been immunized. Dr J D Rolleston, in a lecture on the prevention and control of diphtheria, delivered at the Royal Institute of Public Health on October 28th, 1924, referred to this subject. At the present time, he said, the prevalence of diphtheria in London was unusually high, as was illustrated by the fact that on October 25th, 1925, there were 433 more cases of this disease in the Metropolitan Asylums Board hospitals than on October 25th, 1924, the figures being 2,413 this year, as compared with 1,980 on the same day of the month last year. The marked decline in New York City might, he thought, in all probability be attributed to the extensive employment of toxin antitoxin. After a short account of the etiology of diphtheria to indicate the chief factors in its spread, Dr Rolleston discussed its prevention under the headings of general measures, such as isolation and disinfection, determination by the Schick test of those who were susceptible, and then immunization, either passively by diphtheria antitoxin or actively by toxin antitoxin or meroxin. The futility of the administration of antitoxin by mouth, to which he had drawn attention many years ago (*BRITISH MEDICAL JOURNAL*, 1906, 1, p. 738), had recently been proved by the Schick test, a positive reaction being in no way affected after administration by mouth, while it was immediately rendered negative by subcutaneous injection. The inefficacy of rectal administration of antitoxin had been established in the same way. Both active and passive immunization involved certain drawbacks, but he had no doubt that more complete and permanent results were to be obtained from the use of active immunization. Valuable as active immunization against diphtheria might be, it ranked lower in the scale of preventive methods than vaccination against small-pox, inasmuch as diphtheria antitoxin was a remedy which infallibly arrested the disease if used within the first twenty-four hours, whereas in small-pox there was no treatment, however early applied, which would modify the course of the disease. The practitioner, therefore, was not under the same moral obligation to recommend active immunization against diphtheria as he was to urge vaccination against small-pox. At the conclusion of the lecture the various reactions of the Schick test were demonstrated in nurses in whom it had been recently applied.

LORD DAWSON

At the autumn convocation of McGill University, Montreal, on October 6th (as briefly announced in our issue of October 10th), the honorary degree of Doctor of Laws was conferred upon Lord Dawson of Penn, G C V O, M D. The ceremony took place in the presence of a great gathering of the faculty, students and of graduates, many of whom had served with the Canadian Army Medical Service overseas. Lord Dawson was presented by Dr Charles F Martin, Dean of the Medical Faculty, who, after reciting the visitor's academic distinctions, referred to his great reputation in the medical world and his services to medical education. Sir Arthur Currie, Principal of the University, then conferred the degree. Lord Dawson, who was enthusiastically received, paid a high tribute to the work of McGill medical graduates at the front. McGill, he said, was the first university to send a fully equipped hospital to the seat of war, and, what was even better, that hospital established a reputation unsurpassed for professional achievement, organization, and public spirit. The hospital was in his zone of work as consulting physician, and he never went there without being inspired and cheered. No part of the success was due to the great leadership of

General Balfour, and there were many dark days which tested faith and courage. Lord Dawson went on to speak of the value of university training. The university, he said, was a factor of increasing importance in national life, for advances in knowledge and discovery demanded from those who wished to succeed in any sphere the educated mind. Not that a university should concern itself too closely or too early with future vocation, rather should it give the undergraduate the trained mind on which technical knowledge could be built. A university was not an emporium of facts, but a place to train mind and character. In the Medical Faculty at McGill he had found, not only an admirable system of instruction to meet the many needs of modern science, but a conception of teaching which aimed at training the mind to think well and wisely. The influence of a university was the more needed at a time when brilliant and rapid advance in invention was apt to obscure the things of the spirit. The *Montreal Star*, in an appreciative leading article, says that Lord Dawson laid his finger with unerring accuracy upon the crux of the whole situation in what he said about the 'varsity spirit, and the need for cultural, not mere commercial, training. During his visit to the United States Lord Dawson has since received—in company with Professor V Putti of Bologna, Sir W Arbuthnot Lane, Professor W Blair Bell, Mr Philip Franklin, Dr William Cornall, and Dr Edward Dennis—the honorary Fellowship of the American College of Surgeons.

THE M R C P LONDON

As noted in the report (p. 871) of the meeting of the Royal College of Physicians of London on October 29th, certain alterations have been made in the regulations relating to the examination for the Membership of that College. It may be remembered that the age for admission was fixed last July at 23 years, one of the changes now made is designed to meet the case of candidates engaged in special branches of medicine. In future a candidate who has attained the age of 30 years and who can produce testimonials as to moral character, conduct, and general and professional attainments, will be permitted to submit published work, and if the Censors Board decide that such work is of sufficient merit they may excuse a candidate the whole or part of the usual examination, or may modify it as they think fit. The rule hitherto in force was that any candidate who was a Licentiate of the College or who had obtained at any university a degree of M D or M B registrable by the General Medical Council, might be admitted to the examination for the M R C P. The Censors Board had power to determine in the case of each candidate the nature and extent of the examination, by a new by-law now adopted the College reserves to itself the right to admit to the examination other candidates on the recommendation of the Censors Board. The number of candidates applying for admission to the examination has for various reasons recently increased, and the President and Censors have now been given power to fix such additional times or other times for the various parts of the examination as may be required for its proper conduct. Hitherto a candidate who failed had to wait for six months, in future a candidate may be admitted to a subsequent examination after the lapse of such a period as the Censors Board may decide. With the exception of the new by-law allowing candidates under certain conditions to submit published work in place of part or all the examination, the general effect of the alterations is to give greater elasticity to the President and Censors in admitting candidates to the examination. The new regulations come into force at once, and copies can be obtained on application to the Registrar, Royal College of Physicians, Pall Mall East, London, S W 1.

MENTAL HYGIENE

ADDRESS BY LORD BIRKENHEAD

A MEETING, which was attended by many distinguished persons, to further the aims of the National Council for Mental Hygiene was held at the house of the Royal Society of Medicine on November 2nd. Sir Courtenay Thomson, who presided, explained that the activities of the Council embraced the improvement of the mental health of the community, the study of the causes underlying congenital and acquired mental defect and disorder, the study of criminality, dependence, vagrancy, and prostitution, in so far as they were failures of adjustment by reason of mental trouble, and the study of the mental hygiene of child life. The Council also sought to secure a more important position for the study of psychiatry in the medical curriculum, and the closer association of psychiatry with general medicine.

The Lord of Birkenhead said that he could offer only a few general observations from the point of view of a layman. The angle from which the lawyers examined mental extravagance or weakness was different from that taken by the physician, and so it happened that in recurring cycles the physician challenged the point of view of the lawyer. The legal test was laid down many years ago in the famous *M'Naghten* judgement, which never received, he thought, the complete support of the contemporary medical profession, and had been even more frequently challenged of recent years. That controversy was one of much interest, and he could, if it were germane to the objects of that meeting, attempt some more detailed defence of the legal view than had recently been put forward in the face of medical criticism. He wished to make it plain that he was not there to usurp the functions of his distinguished and untiring colleague, the Minister of Health, and he was a little anxious lest Mr. Neville Chamberlain should think that he (Lord Birkenhead) was breaking into pastures of which he was the efficient shepherd. Moreover, at the present time a Royal Commission was sitting to consider the whole question of lunacy law and administration, and it would obviously be very improper for him to enter into any discussion of the legal position which might be held to anticipate the findings of that very influential and able Commission. He would only say that he welcomed the opportunity of expressing his view that everything ought to be done to encourage the curative treatment of persons suffering from mental disorder. In this respect the National Council for Mental Hygiene could play an important if not an indispensable part in the education of public opinion.

It was very necessary (Lord Birkenhead continued) to escape from the old idea of an asylum as a place of incarceration, it ought to be regarded as a mental hospital and an institution whose primary function was the treatment of mental diseases of every kind. It had been too long the public habit to regard an asylum, not, as the classical origin of the word would suggest, as a shelter, but as hardly distinguishable, save on the purely moral side, from a prison. Such a conception was barbarous and out of date. When once the importance of curative treatment was realized it would be understood that the desire, which still persisted, to keep the mental patient out of the mental hospital for as long as possible was prejudicial to his recovery. It was, in fact, to deprive him of proper treatment at the stage in his disorder when it was most likely to be availing. Everyone would regard it as a foolish thing to adopt any such method in the case of physical disorder, and he was not aware of any circumstance which differentiated physical from mental ailments in this respect.

In psychiatry, as in other branches of medicine, progress depended upon study and research, and the influence of the Council could not be better employed than in stimulating scientific work in this field. It was surprising how difficult it had been found, both by doctors and lawyers, to analyse those gradations which formed the debatable land between sanity and insanity, between such disturbance of the mind as could properly exclude a man from responsibility for his own affairs or the affairs of others,

and such a degree of eccentricity as involved no real disqualification. The lawyers had quarrelled over this debatable ground for generations, quite recently, by the way, it had become necessary to examine cogitatively though not identically problems in relation to the state of mind produced by drunkenness. The close alliance between quickness of mental parts and insanity had been remarked by the national poet, and he supposed that, despite all modern investigation, it still could not be explained how a slight alteration in an infinitesimal cell could make the difference between the genius and the lunatic. He doubted also—though he knew himself little competent to offer an opinion—whether medical science or nursing technique had made the advance from the preventive point of view in dealing with mental cases that it had made, even within his own lifetime, in almost every variety of physical ill. Yet of all the terrible consequences that were produced by pathological causes those affecting the mind were the most poignant.

He rejoiced to notice the international character of the mental hygiene movement. The National Council in this country was one exhibition of a movement which had extended in the United States and Canada, in France, and he thought also in Italy. It was a hopeful sign that the scientific minds of so many countries were devoting themselves to this common problem. The problem was beset at every stage with complications and anxieties. Take the case of the indiscriminate breeding of weak-minded persons. Just those sections of the community whose children would contribute most, in reasonable expectation, by the excellence alike of their bodies and their minds, to the public well-being had ceased, under the stern pressure of material stringency, to produce children in the numbers in which their ancestors had produced them, and this falling off of the most admirable stock in our population had coincided with the multiplication of stock by fathers and mothers whose children from the nature of the case could be no strength to the social order or the State.

Lord Birkenhead concluded by saying that the National Council seemed from its report to be working on the right lines. The last year had been spent in the difficult task of requiring precise information as to the resources already in possession and the degree in which they could be improved. These reports seemed to suggest that up to the present it had not been realized that pathology, whether concerned with the mental or the physical, was one and indivisible. It was the purpose of the Council to make this elementary truth known. During the last twenty or thirty years there had not been, even among the highly instructed doctors whom the great universities had produced, a complete realization of this scientific truth which, when once it was stated, became self-evident and needed no technical equipment to make clear. If a citizen was disabled so that he could not function if he could not play his part in the social and public life of his country, it mattered not at all whether the cause of his disability was a disordered stomach or a disordered mind. The same human and scientific processes which many decades of wise and prudent research had placed at the disposal of the citizens in the case of physical ailments ought equally to be available in the case of a menaced mind. One would have thought, indeed, that if any distinction was to be drawn at all, the argument in the latter case was almost *a fortiori*.

Sir Maurice Crichton echoed Lord Birkenhead's statement that a more enlightened way of treating mental disorder would not be forthcoming until it was appreciated that there was no fundamental difference between the disorders of the mind and of the body. He believed that the vast amount of mental disorder that filled the mental hospitals was preventable. His experience of fifteen years in mental hospitals in treating the later stages of mind disorder had led him to see that the really effective place in treatment lay in the early stages and in consequence it was to the preventive side that he had directed his energies during the last twenty years. He added that much mental disorder in early life had its beginnings in childhood, and in consequence he looked forward to the day when educationists would take an increasingly active part in the work of the National Council.

Dr W A Potts referred to the great ignorance existing with regard to mental defect yet mental defect was not less important than lunacy, and was interwoven with the whole social problem. The present haphazard treatment or the moral imbecile was lamentable. Possibly the Mental Deficiency Act might be capable of amendment, but far more important was the proper carrying out of that measure. Even the medical profession wanted educating. The facilities available for the study of mental defect were of the slightest. There was practically no instruction at all for the medical student, and for post-graduates there was only the course for the diploma in psychological medicine, which was long and difficult, and was intended only for specialists.

Lord Southborough, treasurer of the Council, made an appeal on behalf of the Council's "empty purse." The subscriptions and donations for last year totalled little more than £400, barely sufficient to meet the everyday expenses of clerical work.

The report for the year, which was distributed at the meeting, included the reports of three subcommittees which had been appointed—one on the question of the prevention and early treatment of mental disorder, the second on the care, after-care, and treatment of the insane, and the third on mental deficiency in relation to crime. The evidence given to the Royal Commission by the Council (of which a report appeared in the *BRITISH MEDICAL JOURNAL*, May 30th, p. 1015) was also set out at length.

ST THOMAS'S HOSPITAL MEDICAL SCHOOL

STUDENTS' WAR MEMORIAL

On Monday, November 2nd, H R H the Duke of York laid the foundation stone of the new College House Extension and Students' Club which is to be erected as a memorial to the students and members of the staff of St Thomas's Hospital who fell in the war. The building will face the main hospital buildings in Lambeth Palace Road. It will contain club rooms and seventy-two bedrooms for students and members of the resident staff.

The Duke of York, on his arrival at noon, was received by the Hon Sir Arthur Stanley, treasurer of the hospital, and Sir George Makins, chairman of the War Memorial Committee. After inspecting the guard of honour of the medical unit of the University of London Officers' Training Corps, he was conducted to the site of the new building, where Princess Helena Victoria was present, together with the Lord Mayor and Sheriffs, the Bishop of Southwark, the Mayor of Lambeth, and the principal members of the hospital and medical school staffs. Sir Arthur Stanley made a number of presentations to the Duke, and delivered a brief speech of welcome, in which he recalled some of the loyal associations with the hospital.

After prayers by the hospitaler and dedication of the work by the Bishop of Southwark, Sir George Makins invited the Duke to lay the foundation stone. He recalled that St Thomas's Hospital and its medical school suffered grievously in the great war. Of those connected with the hospital 1,481 served, including 214 members of the nursing staff. Of the 81 who fell 8 served as combatant officers, 18 medical officers were killed in action, and 10 more died of wounds. It was felt that no monument could be more fitting than this, which would bring their memory constantly before future members of the school during the time they spent working in the hospital and school. The provision of this hostel was, moreover, an indication of the gradual conversion of the University of London, of which the school was a constituent college, from a purely teaching and examining body to a complete university with residential accommodation for its students. In planning and financing these developments they had had the active support of the treasurer and governors of the hospital, who realized the importance of the project to the welfare of the institution as a whole.

The Duke of York then laid the foundation stone in position, and tested it with the level used by Queen Victoria when laying the first stone of the present hospital building in 1868. He said that no better way of honouring the memory of the hospital's gallant dead could have been

chosen than by providing this club and hostel for future generations of students. In conclusion he handed over to the treasurer for the benefit of the hospital patients the wireless installation presented by readers of the *Daily News*.

Old Students' Dinner

The annual old students' dinner was held at the Hotel Victoria on the previous Friday evening, under the chairmanship of Mr Samuel Osborn, F.R.C.S., who was supported by nearly 200 past and present members of the hospital and guests. Among the company, besides those mentioned below, were Lieut-General Sir William Ickburgh, D.G.A.M.S., Air Vice-Marshal David Munro, R.A.F.M.S., Dr T Vincent Dickinson, Master of the Apothecaries' Society, Sir R Havelock Charles, Sir Hector Mackenzie, Lord Riddell, and Sir Harold Downes.

After the King's health had been honoured the chairman, in proposing prosperity to St Thomas's Hospital and Medical School, recalled that it was fifty-seven years since he entered as a student in the old medical school buildings in the Surrey Zoological Gardens, he was the last resident accoucheur in the old hospital buildings and the first house-physician in the new. Sir Arthur Stanley, responding on behalf of the hospital, spoke of the trials of a treasurer in trying to keep up with the many new needs which follow in the wake of new discoveries in medical and surgical science. "In the old days a man who had a bad leg was treated for a bad leg, but now..." In responding for the School the Dean, Sir Cuthbert Wallace, mentioned some old friends who had died during the past eighteen months, in particular, a deeply respected teacher, Professor Shattock, and an old student, Dr Clement Dukes of Rugby, who founded the science of school medical officership. Since the war the average entry of students at St Thomas's had been 87, with an average total of 454. The Government grant he said, was now of the utmost importance to medical schools, which could not carry on without it. Sir George Makins, who also replied, expressed the thanks of the War Memorial Committee to the old students for subscribing so generously towards the building of the students' club and residential hostel—a thing that he and others had dreamt of for many years past, and no expressed the gratitude of the Medical School to Sir Arthur Stanley and his fellow governors for their unwearied help and encouragement. Sir George Makins then passed to his next duty, of proposing the chairman's health, and mentioned Mr Osborn's services to the cause of ambulance and first-aid work in many seats of war.

The custom of having a short toast-list and short informal speeches always contributes greatly to the pleasure of those attending the St Thomas's Hospital annual dinner.

England and Wales.

TUBERCULOSIS IN LANCASHIRE

In the report for 1924 of the central tuberculosis officer for Lancashire (Dr G Lassant Cox) special attention is paid to the value of x-rays in diagnosis and treatment, and sixteen skiagrams are inserted to illustrate various conditions. The number of x-ray examinations made by the tuberculosis medical staff during 1924 was 4,205. The first x-ray apparatus was installed at the Ashton-under-Lyne dispensary in November, 1920, and in the succeeding three years one dispensary in each area was equipped with a set to be used by the tuberculosis officers, who have thus become skilled radiologists. Dr Lassant Cox sets out the following advantages of having an x-ray apparatus in a tuberculosis dispensary. The tuberculosis officer, being the radiographer, is able to make screen examinations and take skiagrams personally as often as required, the patient can be examined radiologically and clinically at the same visit, thus saving unnecessary journeys and expense, and the tuberculosis officer being able to examine the patients frequently can build up a knowledge of x-ray appearances and their clinical significance. The x-ray report is thus combined with the history, symptoms, physical signs, and sputum examination, with great benefit.

to diagnosis. The point is emphasized in the report that such x-ray examination must be used as a routine procedure, if only a few exceptional cases are selected for examination the full value of the method is not realized, since x-rays often reveal the presence of some unsuspected condition when other means of diagnosis have given no assistance. In many early cases, though not in all, a good skiagram will supply definite evidence of the existence of the disease, and Dr Lissart Cox adds that in his experience it is rare for a lesion to be found by the ordinary clinical methods which was not demonstrable by an x-ray examination. There was a decline in 1924 in the deaths recorded as due to tuberculosis and in the new cases notified, in both pulmonary and non-pulmonary tuberculosis the death rates were the lowest hitherto recorded. The general decline in the disease is the more satisfactory in view of the widespread unemployment and the defective housing conditions. Omission to notify cases is now much less frequent. In 1917 18 per cent of the deaths from pulmonary tuberculosis occurred without the statutory notification having been made, in 1924 this figure had been reduced to 5 per cent. This is attributed to the cordial co-operation between general practitioners, medical officers of health, and the tuberculosis medical staff in a comprehensive scheme which includes adequate means for expert diagnosis and sufficient beds for treatment. The tuberculosis department, which has actively co-operated in propaganda work, now possesses its own cinematograph films for exhibition. A special film has been prepared to illustrate the life of patients at the county council sanatorium at High Carley and the children's sanatorium at Ulverston. A number of lantern slides and photographs of county sanatoriums, hospitals, and dispensaries have also been acquired, the majority having been made by a member of the tuberculosis clerical staff. The census of the housing conditions of patients showed that the proportion of infectious patients sharing a bed with one or more persons was 8.8 per cent in 1924, as compared with 10.1 last year, 13.1 in 1922, and 17.1 in 1921. This very considerable improvement was due mainly to the loan of bedsteads and mattresses from the stock purchased by the county council to patients unable to provide these for themselves. In the county eighteen voluntary care committees were at work, covering a population of nearly 800,000. Where these committees have not yet been formed their place is taken by the dispensary staff. The new hospital at Rufford, for about fifty patients, will shortly be ready for occupation, it will include a plaster room and an operating theatre for the treatment of non-pulmonary tuberculosis. Better dispensary premises have been obtained at Chorley and Farnworth, while additional institutional accommodation for advanced pulmonary cases will also be available shortly. Statistical research work and the investigation of new methods of treatment are being carried on by the staff, the inquiries include investigation of the fate of young children of tuberculous households, at the request of the Joint Tuberculosis Council of England and Wales, and the fate of young children of tuberculous families for Professor Calmette of Paris. The distribution of pulmonary tuberculosis in Lancashire is also being studied with particular reference to cotton-weaving, cotton spinning, and coal mining. The cost of the county scheme for tuberculosis, apart from Government grants, has required a county rate of slightly over 1½d in the £ for the current year, 1925-26.

THE MIDDLESEX HOSPITAL

The structure of the Middlesex Hospital was declared a short time ago to be unsafe, and the board of management, after making a forcible appeal to the public, has resolved to prepare for the erection of the new building by demolishing the west wing. It provides for 200 patients male and female, and the hospital authorities have been fortunate enough to make arrangements by which they get temporary possession of the old Sick Infirmary in Cleveland Street near by. When the alterations there are complete it will provide 200 beds, and also operating theatres, an

x-ray room, a staff room, and offices. It is hoped that this building will be ready to receive patients by January next, and that by that time further progress will be made in raising the £500,000 estimated to be required for the new hospital buildings. The amount at present received is £210,000.

CENTENARY OF UNIVERSITY COLLEGE, LONDON

University College, London, will celebrate its centenary in the year after next. The famous letter of Thomas Campbell, the poet, to Mr Henry Brougham (afterwards Lord Brougham) suggesting the creation of a University of London was published in the *Times* of February 9th, 1825, but the foundation stone of the building in Gower Street for the University of London was not laid until April 30th, 1827. With the approval of the University of London, as it now exists and with which the college was incorporated in 1907, a centenary appeal for a sum of half a million has been launched. Of this amount nearly half (£225,000) is needed for the endowment of teaching in the faculties of arts, laws, science, and engineering. A sum of £25,000 is needed for the completion of the Gower Street front in harmony with the design of Wilkins for the main buildings and according to plans approved by the Royal Fine Art Commission, £15,000 is needed to complete the equipment of the chemical laboratories, the erection of which, at a cost of £102,000, was completed in 1914. New buildings are needed also for the departments of zoology and comparative anatomy, and a site is already in view. Considerable expenditure is necessary also for the reconstruction and re-equipment of the engineering departments, for the libraries, and for the erection of a great hall. For the last named a site has been acquired at the east side of the college in Gordon Street, and a design for it has been prepared by Professor A. E. Richardson. The honorary secretary of the Appeal Committee is Mr Walter Seton (University College, Gower Street, W.C.1).

ST LUKE'S DAY SERVICE IN NOTTINGHAM

Under the auspices of the Nottingham Medico-Chirurgical Society a special ceremonial service was held on Sunday, October 18th, St Luke's Day, at St Mary's Church, Nottingham. There was a large congregation, including the President (Mr H. Bell Lawse), the council and members of the Medico-Chirurgical Society, the Mayor and Sheriff, who attended in state, members of the city council and board of guardians, the town clerk, and corporation officials. The sermon was preached by the Bishop of Durham (Dr H. Hensley Henson), who asked what had been the influence of Christianity on the theory and practice of medicine, apart from the phenomenon of faith healing which was not distinctly Christian. How had religion influenced what had been done in the march of physical science? Had they gained or lost by the influence of Christianity in the matter of physical healing? Christianity had its birth in a superstitious age. Religious confusions at that time facilitated the growth of superstition, and superstition had found its most fruitful soil in physical ailments. The first effect of Christianity was to strengthen the non-scientific element in medicine. The assumed connexion between sin and disease led people to seek relief more from religion than science. Christianity always carried with it the promise of better things. The unselfishness and enthusiasm which medical science today had for healing was the gift of Christ's religion. The medical profession might still have a lingering resentment against the ecclesiastical discipline of the past and the subordination of medicine to theology. It was often the rule first to correct the ailments of the soul, and then attend to physical ailments. But the humanity of the physician had triumphed over the discipline of the Church. In view of past history there was nothing surprising in the fact that medical men might have regarded with considerable suspicion the suggestion of recognizing in the clergy friends and even colleagues. The Bishop concluded by saying that, "In the fellowship of pain all are one, and all are one in the charity of the Eternal Father and in the duties of human life."

Scotland.

EDINBURGH UNIVERSITY GENERAL COUNCIL MEETING

The statutory half-yearly meeting of the General Council of the University of Edinburgh was held on October 30th, when Principal Sir J. Alfred Ewing was in the chair. A proposal to institute an honours course in experimental psychology for the degree of B.Sc. was approved. The Principal stated that by the generosity of the late Lord Abercromby the University was about to found a chair of archaeology. Six months ago, on account of heavy expenditure in connexion especially with the building of the new chemical laboratory, the University had been involved in a heavy burden of debt, but the situation had been considerably altered by generous donors. Recently the announcement was made that the Chancellor of the Exchequer had allowed the inclusion in the estimates for the current financial year of a sum to supplement the annual grant to the universities of Great Britain. It was not yet known what the amount would be, but it would undoubtedly do much to prevent the painful necessity which had existed during the last few years of sometimes reducing expenditure below the standard compatible with efficiency. There were, however, inevitable expansions in subjects and in methods which would necessitate annual demands for maintenance, staffing, and equipment, and it was still necessary to impress on the friends of the University the continued need for help. The Business Committee submitted a report in regard to the doctorate in different faculties. The council adopted, among others, the following recommendations of the committee:

That every graduate should have a right to proceed to the degree of Doctor in his own faculty, under appropriate regulations, the degrees of D.D. and LL.D. included.

That a graduate with honours should be permitted to proceed to the degree of Doctor within a shorter period after taking his degree than the holder of an ordinary degree.

That an approximately uniform standard should be aimed at for the degree of Doctor in all faculties.

That degrees of Doctor obtainable by examination might also be given *honoris causa*, but that in the latter case they should be granted only to persons distinguished in the subject of the degree.

That in the case of persons who merited honour from the University but whose distinction was not connected with any branch of learning the honour should take the form of a new degree designated in such a way as to mark eminence in public service.

That the period of two years required to elapse between the degrees of M.B. and M.D. is too short while the period of five years required in the case of D.Litt. is too long, and that a uniform period should be struck in the case of all degrees of Doctor.

Among the changes in the teaching staff intimated were the appointment of Mr. George Buchanan, M.B., to the lectureship in bacteriology, of Dr. W. T. Benson as successor to the late Dr. Claude B. Keir as lecturer on infectious diseases, and of Dr. J. M. Woodburn Morrison as holder of the newly established lectureship of electrical therapeutics and radiology. It was intimated that the number of students during the academic year 1924-25 had been 3,864, as compared with the highest number of 4,886 in 1920-21, and as compared with an average of 3,340 in the five years preceding the war. The number of medical students during these three periods had been respectively 1,252, 1,967, and 1,340.

EDINBURGH CLINIC FOR CRIPPLED CHILDREN

A meeting was held in Edinburgh on October 28th, under the auspices of the Edinburgh Committee of the Chartered Society of Massage and Medical Gymnastics. The object of the meeting was the establishment in Edinburgh of a clinic where massage and allied treatment could be available, more especially for those who could not afford the ordinary fees for private treatment. The intention is especially to deal with crippled children whose treatment should continue throughout the whole period of their growth. Mr. W. A. Cochrane, M.B., F.R.C.S., presided over a large attendance, and said that a well-known authority had recently

asserted that 75 per cent of crippled children could be made well. It had been said that the crippled child was made, not born, and this was true, for he was not so much a cripple as allowed to become a cripple, and early diagnosis and early treatment of the conditions responsible were of vital importance. Demonstrations of remedial exercises and of country dances formed features of the proceedings, and a cinematograph film was shown illustrating the benefit that could be derived from continued treatment in a case of infantile paralysis affecting the arm and leg. The Rev. T. Ritchie Barnett described the operation of a scheme for the treatment of crippled children in England. Two or three counties, he said, were grouped together, and the first thing necessary was a central orthopaedic hospital, where children could be kept without any limit as to time. After discharge they went home and returned at intervals for further treatment, but the child was never lost sight of. Small orthopaedic departments should be established in two or three little hospitals in the area, where local necky clinics could be started. Such a scheme could not be carried out at present in the large general hospitals, because already they had long waiting lists. Even if beds were available children could not, as a rule, be kept in hospital sufficiently long for the prolonged treatment required. Open-air wards were also a necessity in order that sunlight and fresh air might form part of the treatment day and night in all kinds of weather. In such open air wards education could be continued in the case of children who were retained for long periods. The committee desired to appeal to the public, for it was inconceivable that Scotland should be behind any other country in such a good form of work, and it was surprising that Scotland had not yet started this system of linking-up clinics. The Rev. Dr. Harry Miller said that the building of a gymnasium in the Pleasance Settlement would be begun in a few days, and it was hoped that a clinic such as had been described would be opened.

Ireland.

ULSTER MEDICAL SOCIETY

The opening meeting of the Ulster Medical Society for the session 1925-26 was held in the Medical Institute, Belfast, on October 29th. The retiring president, Dr. J. Singleton Darling (Lurgan), thanked the fellows for their active and warm support during the past year, and introduced his successor, Mr. James A. Craig, F.R.C.S. The president proposed a hearty vote of thanks to Dr. Darling for his conduct in the chair, his hospitality, and his great aid to the society, this was seconded by Dr. Caldwell and passed with acclamation. The president referred in feeling terms to the loss the society had sustained during the year by the deaths of three of its fellows, Dr. J. C. Martin of Portrush, Dr. William Monypenny of Belfast, and Dr. John McLiesh of Belfast, and then read his opening address on the retina in constitutional disease. The retactions of the retina, Mr. Craig said, to disordered and bodily conditions showed the close relation between ophthalmology and general medicine. The use of the ophthalmoscope and perimetry in pituitary and brain affections was an illustration of this connexion. The retinal arteries could be used for the study of the circulation, as in Brillant's experiments on the tension of these vessels. The ophthalmoscopic appearances in hyperpiesia and in arterial sclerosis were of great importance. Sclerosis of vessels of the size of the retinal arteries played an important part in the condition of general hypertension, sometimes such patients felt quite well, but observations made with the ophthalmoscope afforded an index of the condition of the arteries throughout the body. Mr. Craig went on to observe that the question how far the arteries of the retina were an index of the condition of the cerebral arteries was also a matter for consideration, and quoted the work of Foster Moore and Adams, there was a parallel between arteriosclerosis and retinal thrombosis on the one hand and temporary aphasia and paresis and cerebral thrombosis on the other. The danger of a sudden fall of blood pressure in a case of arterio-sclerosis in both was mentioned. Mr. Craig then

gave an analysis of fifty consecutive cases of retinal hemorrhage found in persons complaining of eye symptoms and referred to the necessity of a full general examination in all such cases. In reviewing the subject of renal retinitis he referred to the close resemblance between the symptoms of eclampsia and those of acute lead poisoning, the contraction of the retinal vessels and blanching of the fundus were found in both in the acute stage. The existence of diabetic retinitis as a distinct entity was described, and it was suggested that co-ordinated investigation by the oculist, the physician, and the biochemist might be expected to add to our knowledge of the essential nature of the fundus changes associated with glyceremia. The paper was illustrated with lantern slides, showing the various pathological conditions. A hearty vote of thanks to the lecturer for his paper was proposed by Mr W. M. Killen, seconded by Professor Thomson, and passed with acclamation.

CARE OF THE INSANE

Suggestions for improvements in the care of the insane have been made by Dr Donelan, resident medical superintendent of the Grangegorman Mental Hospital, Dublin, in a report submitted to the joint committee of management. The report contains his replies to the questions asked by the Commission for the Relief of Destitute Sick and Poor. Dr Donelan stated that the institution was overcrowded to the extent of 250 patients, and 160 further patients were housed in the old Grangegorman Prison, which was utterly unsuited for insane persons. He suggested that additional accommodation might be obtained in some of the disused buildings of the adjoining North Dublin Union. A modified form of the Scottish boarding-out system, under which the patients would continue under the supervision of the hospital authorities, might be adopted. The insane and mentally deficient he had seen in county homes appeared to be very inadequately provided for. They should be cared for in establishments specially provided for them. He did not think it mattered very much whether the cost of maintaining the insane poor was paid out of the rates or the taxes. He was of opinion that mentally defective children should be cared for under strict supervision in special institutions by teachers trained in the art of eliciting whatever exceptional faculties existed and developing them to the best advantage. He regarded the matter of making provision for mentally defective children as being by far the most urgent question now appertaining to the humane consideration of the authorities. Mental hospitals were utterly unsuited for defective children, and no worse place could be found for a helpless child than amongst a crowd of insane adults. He was in favour of local as against State control of mental hospitals.

WEXFORD COUNTY HEALTH BOARD AND VACCINATION

Wexford County Health Board declined by a vote of four to three to comply with a Local Government Department order to enforce the vaccination laws. In August the board adjourned the question of taking action against defaulters until provision would be made in the law to meet cases of conscientious objectors. The department pointed out that the board had no power to abrogate the existing law and intimated that unless defaulters were compelled to comply with the law the Ministry would take proceedings against the board by way of mandamus, the cost of such proceedings to be charged against the members who, by their action, will have involved the rates in such unnecessary expenditure. At an adjourned meeting of the Health Board a further letter was read from the Department of Local Government and Public Health, stating that, before instituting proceedings to compel the board to enforce the Vaccination Acts, the Minister would draw attention to the remarks of the judge in a former case against a board of guardians in 1915, in which he stated that guardians who persistently refused to enforce the Acts would do so at the peril of being obliged to pay the costs of proceedings to compel them to discharge this duty. On a division the board decided by five votes to four not to enforce the Vaccination Acts.

Correspondence.

RHEUMATIC INFECTION IN CHILDHOOD

SIR,—The report of the discussion which took place at the Annual Meeting at Bath on rheumatic infection in childhood (*BRITISH MEDICAL JOURNAL*, October 31st, p. 788) stimulates me to refer to one or two points in connection with this most important subject.

Two or three of the speakers, especially Dr Vincent Cortes and Dr Thomas, concentrated their remarks more especially upon the pre-rheumatic period of the disease, and I venture to believe that they came very close to the central problem of child rheumatism. Experience gained in dealing with the children attending a large children's out-patient clinic leads me also to believe that the close study of the out-of-health states which precede, in the large majority of rheumatic cases, the first frank attack of rheumatism will go a long way towards a better understanding of the etiology of this crippling disease.

There has been in the past, I think, some loss of time in concentrating too narrowly upon the infecting agent itself, for even if it were finally proved that the disease is the result of an infection by the diplococcus of Poynton and Payne—and there must be few, if any, at the present time who would deny it—yet even then we should be a long way from understanding the reasons why so many children fall victims to the disease, and that, after all, is the urgent question awaiting solution. In a communication to the *Lancet* (August 2nd, 1924) I tried to draw attention to the fact that in a large majority of all cases of child rheumatism the first attack of frank rheumatism is preceded by a period of months or years of impaired health, and I attempted to show that this pre-rheumatic impaired health was due to toxic influences, and that the child was definitely a toxic child. Such children come within the class of debilitated children, and, indeed, form the majority of all such children, and I endeavoured to show, by comparing the pre-rheumatic histories of the frankly rheumatic cases with the states of impaired health of the debilitated toxic child who had never suffered with frank rheumatism, that there was so close a relationship between them that one was driven to believe they were the same, and I am entirely in agreement with Dr Cortes when he says that such children make up about 25 per cent of the cases attending a children's clinic.

It is in this type of child—the debilitated toxic child—that rheumatism arises. I would insist that this state of toxic debility is not related to rheumatism in the same way as the “run down” state of health is related to the “catching” of some infection. The relationship is far more intimate and close than that, and one has only to remember the identity of many manifestations common to both states—namely, the fleeting limb pains, lateral chest pain, tired feelings, abdominal pain, pillow, digestive disturbances, more especially loss of appetite and chronic constipation, and the great frequency of nervous unrest and irritability of temper—to realize how near the relationship is. If it is therefore true that frank rheumatism, with its crises, is a development engrafted upon a preceding toxic state, then it is not unreasonable to believe that the explanation of the toxic state will go a long way towards a solution of the etiology of rheumatism.

I suggested that the toxic state was caused by two main factors—first, a reduction of the tone and resistance of the tissue cells throughout the body, brought about by a long-continued dietetic defect, and secondly, by chronic absorption of toxins through the mucous surfaces into the system due to this loss of tone and resistance, and specially one would emphasize the throat and intestinal tract as important points of entrance. I would, however, venture to suggest that too great importance has been placed upon the throat as the chief anatomical defect. It has not been my experience to find that tonsillitis precedes anything like the majority of rheumatic attacks, nor am I impressed with the suggestion that unhealthy tonsils are more frequently seen in rheumatic cases than in other school children, and

I am not convinced that the early removal of tonsils protects the child from further attacks of rheumatism. I do not deny that the infecting agent may gain entrance by the throat, and accept the statement that the organism of Pointon and Payne has been found in the tonsils, but I cannot help feeling that the problem before us is a much wider one than the decision as to the point of entrance of the diplococcus. In the paper referred to I produced some evidence in favour of the intestinal tract as at any rate a very frequently abnormal part of the body of both the debilitated toxic child and the frankly rheumatic child, and while one has no evidence that the infecting agent gains entrance through the wall of the bowel, yet a close study of these toxic children and the effects of treatment on the basis of chronic digestive disturbance forces one to the conclusion that the intestinal tract is an important factor in the production of the out-of-health condition.

If an explanation on this basis is correct, then I venture to insist that the diet of the young child, from the weaning period onwards, is far and away the most important single factor for our attention, and I am specially stimulated to bring this forward at the present moment, seeing that at the Bath discussion the diet apparently was not mentioned except under the wide term of environment. That other factors play some part, such as damp, bad hygiene, and nervous strain, I doubt not, but it appears to me on reading the report that the dietetic factor is in some danger of being neglected.

Finally, I would suggest that the reason why frank rheumatism much occurs before the age of 5 years is because it takes a considerable time for the toxic debilitated state to be produced, and in a like manner the person who rheumatism becomes increasingly less common after the age of 15 years is because by this age the child has learnt to shift for itself, with the result that a wider selection of food is made.

Possibly, therefore it may finally be found that the eradication of rheumatism of childhood will lie in the direction of a close study of the child between the ages of 1 year and 5 years and a revolutionary change in the diet the infant at present receives, and I would suggest that something will be attained by the provision of a diet containing a much less relative quantity of starch and sugar and a larger quantity of animal fat and animal protein. If this is so, then the problem will require solving by means that are much wider than doctoring and bacteriology—I am, etc.,

Leeds Nov 2nd

C WILFRED VINEY

THE PROPHYLAXIS OF TUBERCULOSIS IN TOWN CHILDREN

The Grancher System

SIR,—At the Tuberculosis Conference in London in 1921 Professor Armand Delille of Paris read a paper on "The protection of children against tuberculosis, with special reference to the Grancher system," the essence of which is the removal of delicate or slightly tuberculous children from homes infected by tuberculosis and placing them with peasant families in the country where they lead an open-air healthy life. He said "2,300 of such children have been sent from Paris alone with the best possible results, and the system is spreading to other large towns in France. An effort is made to keep the child away from home until the source of danger no longer exists. Treated in this way these children almost invariably do well, but if left to themselves it is estimated that 60 per cent of them are of tuberculosis."

The Hastings and St Leonards Tuberculosis Care Committee had thought of the same plan, and was then adopting it, as was mentioned at the 1921 Conference, and since then year by year it has placed some infected children in carefully selected cottages in the surrounding Sussex villages. This was briefly described at the Conference this year. As it gave rise to numerous inquiries at the time and to subsequent letters from different parts of the country asking for further details, it is thought that an account of our work in this direction may be of service to some

of your readers, more especially to those who are members of tuberculosis care committees.

We deal with children from the time when they are just old enough to leave their home, up to about 14 years of age, and, although we send away any child in an early non-infectious stage of tuberculosis whose home conditions are bad, the system is particularly applicable to children living in poor and crowded dwellings, where another member of the family (generally a parent) is dying of the disease, is highly infectious, and cannot, or will not, be moved. As soon as these "contact cases" have been kept under observation for a sufficient time to show that they are definitely failing in health, and not suffering from some temporary ailment, or sickening for an infectious fever, the only safe course appears to be to take it for granted that they have become tubercularized, even in the absence of physical signs, and remove them from the source of danger. Our work is done largely in conjunction with the Guardianship Society of Brighton and the children are visited by its visitors, or by our tuberculosis visitors, according to locality.

Special attention is given to the sleeping accommodation in the cottages, the nature of the food, and care is taken also that the children are not employed in domestic work. They go for picnics and excursions, and thoroughly enjoy themselves, which in itself is conducive to health and they are almost always very loath to return home. They invariably rapidly improve and put on weight. I only remember one exception to this rule, and in this instance the case was complicated by asthma. Their stay is generally from four to five months, or longer if it is considered advisable. If they are obliged to return home too soon they are kept under close observation, and are again removed if they show distinct evidence of relapse.

The cost per child works out at 11s 3d a week on the average. This is the amount payable by agreement to the Guardianship Society for children living in its area. Part of it may be returned to us by parents who contribute to their children's maintenance. The following is an account that came before our Care Committee on October 8th last.

Maintenance of Five Children in the Country

	£	s	d
4 children at 11s 3d	2	5	0
1 child at 5s	0	5	0
	2	10	0

The Grancher system is, of course, only applicable in the spring, summer, and early autumn months. Its more striking advantages seem to be that the home life with people of their own class appeals strongly to the children and then parents in contradistinction to life at a sanatorium, and it is far cheaper, also it leaves more beds for cases for whom sanatorium treatment is essential. Our experience now extending over some years, leads us to consider this method highly satisfactory, and we regard it as one of the most valuable features of our work—I am, etc.,

W BOLTON TOWNSON, M.D.,

Vice President of the Hastings and St Leonards
Tuberculosis Care Committee

October 28th

RECTAL INJECTION OF TARTAR EMETIC FOR BILHARZIASIS

SIR—Dr H F Wilson in Nyasaland published his results of the treatment of bilharzia disease by rectal injections of antimony trihydrate (*BRITISH MEDICAL JOURNAL*, January 28th, 1922, p 137), and Dr J Bancroft Anderson wrote (*BRITISH MEDICAL JOURNAL*, October 17th, 1925, p 700) that since that date he had used exclusively that treatment, and the simplicity, safety, convenience, and efficiency of the rectal administration of tartar emetic appeared to make intravenous injection in bilharziasis no longer a justifiable treatment.

Dr Anderson tried it in two cases. To one he gave 19 grains without unpleasant effect, and to the other, a boy of 17, he gave one injection of 6 grains and the ova disappeared. No doubt Dr Anderson tried it in other cases.

Although all well equipped doctors might not agree that an enemal is simpler, safer, or more convenient than an intravenous injection, rectal injections are undoubtedly more appropriate for nurses and unqualified persons, of Africa, and this method of administration would be preferred by them to intravenous medication, if as efficient I believe that it has been tried by nurses in Nataland, where bilharzia is prevalent, and abandoned.

It was also tried by a doctor in Nataland, and although he did not record his work he concluded that he preferred the intravenous route. The reason why the method is not popular, I think, is that when doses such as 19 grains of antimony trisulphate are given no one has satisfactorily shown what becomes of it, and though apparently efficient at the time examination at a later period has proved that bilharzia disease was still present.

I believe that it would be worth while for a medical man to try rectal injections in a series of cases, recording his results in a manner which would allow of the method being conclusively judged. Wilson showed that the rectum was tolerant of large doses of antimony trisulphate (16 grains), and he suggested rectal injections in bilharzia as an alternative for persons whose veins could not be found either on account of the cold weather or for any other reason, and for children. He gave details of four cases, and his paper was a very notable contribution to bilharzia, and antimony therapy, but he did not record subsequent examinations of the cases, excepting immediately after the treatment was completed. It would be interesting to know how much of 19 grains of antimony is absorbed and how much is returned with the faeces. Antimony is rapidly excreted by the kidney, it would not be too difficult to estimate the excretion by the urine.

Day, in Cairo, showed that bilharzia was so sensitive to antimony that ova already deposited were killed even after the intravenous injections of 1½ grains (100 per cent of the ova were killed after 6 grains). His work proved that the parent worm was considerably upset after a small dose of 1½ grains, but that it required a much larger concentration of antimony trisulphate to kill it, for living ova reappeared after an interval. It does not necessarily follow that because the ova cease for a period to appear in the excreta the parent worms are dead and the disease cured—I am, etc.,

London Oct 27th.

J B CHRISTIANSON, CBE,
MD FRCP

OSTEOPATHY AND CHIROPRACTIC

Sir,—As one who has always claimed freedom of speech, freedom of experimentation, and the freedom of pioneering on new and more or less unorthodox lines, I should like to add my voice as to the way in which the practice of what is called osteopathy should be regarded.

Not a few practisers of this method of treatment have complained to me that the medical profession is too exclusive to allow it to secure light and knowledge from unorthodox sources, that the medical profession is hopelessly behind the times and hitherto in its ideas of treatment, that the whole horizon of the medical profession is bounded by drugs and operations and injections, and that it has no charity towards sensible methods of healing, that there is no hope for the medical profession ever being in line with the natural laws of the universe because there is no profit to be made out of teaching dietary and obedience to the simpler laws of health, that the medical profession is wrong, in that it sets up an exclusive barrier against men who possess power, of healing, and refuses to associate with those who have gifts which are not possessed by the general practitioner.

These and similar complaints have been made to me from time to time. My answer has always been as follows. No man would entrust his life in going down a coal-pit to a wander who had not obtained the recognized skill for his work. No owner of racehorses would entrust his valuable stock to a man simply because he claimed that he had more knowledge of horses than the grooms who had been brought up in orthodox stables. The medical profession is justified in demanding of anyone who wants to set up as a healer that he should prove that, at any rate, he is equal in

general knowledge of diseases and their causes to the least well qualified of medical practitioners.

I have always pointed out that the way is open and a welcome will be offered to any man who wants to teach new methods and to investigate new powers of healing so only that he will first of all prove that he has at any rate that acquaintance with the work of those who have gone before in the pathway of medicine as is possessed by the general medical practitioner, that the medical profession does not object to new methods and new ideas and does not refuse to obtain light from any source whatever, so long as the man who claims to possess it is prepared to offer a full and free explanation of what he claims, and is prepared to allow it to be tested by those who are capable of such investigation.

The medical profession has a sacred lamp to keep right, a sacred trust to guard, and a sacred profession to uphold, and although in not a few cases it has failed in width of mind and charity of outlook, none the less reform must come from within and not from without. Those who wish to enlarge the outlook of the medical profession must be humble willing, first of all, to enter its portals, and then things will be in a different perspective to them and from a wider standpoint and a higher ground of knowledge they will be able to urge their claims.

There can be no State recognition of half qualified men, and there is nothing to prevent any man attaining the knowledge which is required for such qualification—I am, etc.,

London W 2 Oct 27th

JOSEPH OLDFIELD

Sir.—Instead of applying for legal aid to oust the quack, we should see that there is no niche left for him.

The bone setting fraternity has arisen because many medical men do not pay sufficient attention in cases of minor injuries to securing the patient's recovery in the least possible time and with the least possible interference with the patient's normal daily life—that is, with a minimum of rest and fixation. Many doctors no doubt do so, but so long as even a few fail in this respect the stigma remains and is attached to the whole profession. A few neglected cases (by this I mean put to bed and rested unnecessarily) that go to quacks and get cured quickly make much noise. The same results obtained by a medical man are passed over as part of his normal functions—and can do it if he exercises a little common sense and originality and forgets all preconceived notions.

Broadly the treatment is (1) Massage at once. This is most important. (2) Free movement, passive and active, at the earliest possible moment without undue pain. (3) The avoidance of rigid splints and fixation by bandage. A little ingenuity is required for this, but the results are well worth the effort.

Having had numerous injuries for which the usual treatment is rest, and having always managed to continue to play tennis in spite of them, the matter has been impressed upon me, and when I was in general practice I did the same for my patients with highly satisfactory results. If I could do it anyone else can. Let this stigma be removed—I am, etc.,

Reading October 28th

LESLIE POWELL M.B.

Sir,—I recently saw a case of brachial neuritis which had persisted over a year. It had been massaged or shall we say 'manipulated,' very thoroughly for several months without any apparent benefit. We discovered that the patient had glycosuria and hypoglycaemia (blood sugar 0.28 and 0.30 after 50 gr glucose), but curiously enough no other symptoms pointing to diabetes. Under treatment appropriate to the diabetic condition the brachial neuritis elevated up completely in less than a fortnight. Whether this result was *post hoc* or *propter hoc* I prefer that others should judge, as I have not previously had an exactly parallel experience. I suggest, however, that the case points to the necessity for a wide outlook on the part of those who undertake the treatment of disease. If osteopaths claim registration as being competent to treat some

diseases, may I inquire whether birchial neuritis is one of them? If so, does their timing fit them to deal properly with a case like this? If it does, where is the line to be drawn?

Surely, if there is more in manipulative methods than mere of us appreciate, they will receive due recognition and be generally taught to medical students as a matter of course. But to create a new class of partially educated practitioners seems to me fraught with danger to the public. Why should they not all follow Dr. Kelman MacDonald's example and secure a medical qualification?—I am, etc.,

Manchester Nov. 1st

J STALLA DICK

SIR,—The last paragraph of Dr. E. Graham Little's valuable letter (October 31st, p. 815) contains an important warning to the profession on 'the burning question of registration of unqualified osteopaths.' I am not quite clear what he means by the sentence, 'For the profession as an unorganized corporate body to enter the lists I think would be undesirable, but the exercise of personal influence on their local members of Parliament by doctors throughout the country would be a very valuable method of attack.' Does he mean that members of Parliament should be prompted to oppose the movement by individual doctors only, and that corporate bodies like the universities, Royal Colleges, and the British Medical Association should stand aside?

Judging from the reception of the St. Helens and Warrington motion on unqualified practice brought before the Representative Body at Bath in July, I should say that there is very little interest in the topic. The platform on that occasion was quite apathetic, if not actually hostile to the motion and the lead which was then given to the general body of representatives is not likely to induce either the representatives or their constituents to prompt members of Parliament to oppose the registration of unqualified osteopaths.

To me it has always seemed that the British Medical Association is the most suitable body to handle this question. It is a scientific and democratic body, well accustomed to handling medico-political affairs. It also has among its members a large body of insurance practitioners with more or less assured incomes who have no direct financial interest in checking or discouraging unqualified practice and whose judgement on the question of the admission of unqualified osteopaths to the *Register* would be based to some extent on the merits of the question and on the advice given by the leaders of the Association. That advice is not likely to be given, and if Dr. Graham Little is relying on individual effort on the part of the profession to give him support in his opposition to the movement he will be disappointed.

His vision of "strange and unwelcome bedfellows" being thrust upon us may speedily come true—too late for effective action. The breach in the citadel once made, there is no telling who may not claim to enter, and all the elaborate educational and disciplinary scheme of the General Medical Council will become depraved and vitiated.

As a general practitioner I am interested in the last paragraph of Dr. Kelman MacDonald's letter—with the scientific sophistry in the earlier part of his letter. Other pens than mine will no doubt deal. This paragraph states:

'The members of the British Osteopathic Association are not asking for the privilege of signing death or birth certificates, they do not have to sue for fees, they do not want to prescribe dangerous drugs and they have never been prosecuted for malpractice.'

From this I gather that although the osteopath is seeking registration, he is not seeking it so that he may have the privilege of signing a death certificate. The osteopath, after he has done his best for the patient is to leave that task to the general practitioner. Nor does he wish to sign a birth certificate—I presume this means the notification of a birth. This means that the registered osteopath is to leave confinements to the general practitioner. Nor why should the osteopath leave the pregnant uterus out of his sphere of operations? No other organ is more under the control of the autonomic nervous system than the

rhythmically contracting uterus. Has the osteopath no manipulative exercise to mitigate or stop its pains? "They do not have to sue for fees." Like Omar of old, osteopaths "take the cash and let the credit go." They do not want to prescribe dangerous drugs. What does the osteopath do for the raving man in delirium tremens or for the patient writhing in the agony of renal colic? Cases like these are, I suppose, left to the general practitioner. "They have never been prosecuted for malpractice." I do not wonder. They went more or less healthily forth to treat and they do them no harm. But there is a deep and serious side to this question. Is the medical profession as a whole prepared to see the whole basis of modern scientific medicine on which it has been nurtured supplanted by the official recognition of cult based not on a healthy empiricism like that of the old-time bone-setter, but on mystic fancies and intellectual subtleties masked in the terms of modern science? I hope not.

Sir Archibald Garrod, in his admirable Harveian Oration on the debt of science to medicine, said:

"If medicine were to be established upon a scientific basis its structure needed to be firm from the ground upwards and from the sixteenth century onwards the foundation stones and the pillars which form the lower stories, have been cultivated and advanced largely by medical men who saw them to be essential to the progress of their own science and art."

Progress in the sciences will not be arrested by a healthy scepticism and strenuous opposition to these new heresies. State recognition, however, will mean the diversion of money and energy to fitious purposes instead of being utilized for the advancement of science.

The Bishop of Birmingham in his profound and eloquent sermon to the Association at Bath in July, stressed with a sure hand the trend of present-day thought and onlook. Let us be on our guard—I am, etc.,

Warrington Nov. 1st

J. G. MASON

SIR,—I have been very much interested in the recent correspondence on osteopathy in your columns. It seems to me however that too much is being made of osteopathy to the exclusion of a much older movement—namely, Swedish medical gymnastics. Long before the "invention" of osteopathy the Swedish school had commenced to investigate the presence of localized spinal areas of tenderness and muscular contraction, and to treat them with movements. And similarly, to the Swedish school we owe the use of nerve frictions and vibrations (according to the methods of the late Henrik Kellgren), abdominal pectoral and manipulation of the individual abdominal organ, resisted movements for heart cases and paralysis, etc., which the osteopaths either do not use at all or, if they do, apply them with very poor technique in comparison with the Swedish school.

The only part of osteopathic treatment that is original is the technique of replacing minor displacements of bones in the vertebral column. Thus, I frankly admit is a very important discovery, and one that should be brought to the notice of the medical profession as a whole. At the present moment the opinion of the profession may be summed up as (a) minor displacements of vertebrae cannot occur, and (b) even if they could they could not be replaced by the simple methods of manipulations practised by the osteopaths. I have on previous occasions asked for statements in support of these views so far I have never received one. I can assure those who deny the existence of minor displacements in the spine that during the last fifteen years I have replaced several thousands of vertebrae, and that such reposition in a number of cases was a very important factor in the cure of patients—indeed, in some of them a *sine qua non*. I would refer those interested to a number of my contributions in medical journals recently republished in my *Collected Papers on Mechano-therapeutics* (1924).

I cannot understand why there should be the desire to place osteopaths on a level with the medical profession, inasmuch as they have not had the same training. I should like to ask those who advocate this why they limit their sphere to osteopaths. Should not all Swedish gymnast-midwives, electro-therapists, and massagers also get the

same rights? By all means have a register, and legislate so that lack of skill and quackery be actionable, but there I consider the effort should stop—I am, etc.,

London W 1 Nov 2nd.

EDGAR F. CYRIAN, M D Edin

MYXOEDEMA

SIR,—Because of its reference to Howitz of Denmark as having been the first to employ the method of oral administration of thyroid gland in a case of myxoedema, the annotation which appeared in your issue of October 10th (p 657) has called forth from Dr E L Fox a rejoinder in which you are said "to endow a foreigner with what might more justly have been given to Englishmen."

Without any intention of minimizing the excellent achievement of Dr Fox and of Sir Hector Mackenzie in introducing the oral method of thyroid therapy in this country, the separate published records of which appeared in your issue of October 29th, 1892, I desire in the interests of historical accuracy to draw attention to certain facts which appear to qualify Dr Fox's claim. Dr Fox directs your attention to the annotation which appeared in the same issue (p 965) as his and Mackenzie's papers. May I be allowed to call to your notice the letter from Dr Vermeluen which you published in your issue of February 4th, 1893 (p 266)? In this letter Dr Vermeluen stated that Professor Howitz was the first to treat a case of myxoedema by giving thyroid gland by the mouth, and that the results of this experiment were communicated to the Congress of Naturalists at Copenhagen on July 6th, 1892. Particulars of this communication will be found in the *Verhandlungen des 14. Congresses der skandinavischen Naturforscher in Kopenhagen* (p 517). There will also be found a full discussion of Howitz's case, the treatment of which he commenced on March 27th, 1892, and the successful results of which treatment he communicated to the above mentioned congress on July 6th, 1892, in the *Deutsche medizinische Wochenschrift* of March 16th, 1893 (*Ueber die Behandlung des Myxoedems*, p 255), also by the pen of Dr Vermeluen.

Two other extracts from contemporaries of Dr Fox should prove of interest. In a paper on the treatment of myxoedema read before the Edinburgh Medical-Chirurgical Society on February 15th, 1893, Dr R A Lundie spoke as follows:

The first of these cases [treated by the internal administration of thyroid gland] published in this country were those of Dr Mackenzie and Dr Fox, which appeared simultaneously last October. I had independently arrived at the same result but the first to establish the success of this method seems undoubtedly to have been Prof. Howitz of Copenhagen who communicated his result to the Congress of Naturalists at Copenhagen in July last.

The other reference is to a letter by Dr Ehlers which appeared in *La Semaine Médicale*, 1893 (p 59), in which he said "Des le mois de mars 1892 en effet M. Howitz a traité une malade atteinte de myxoedème par l'ingestion de pilules préparées avec des glandes thyroïdiennes de veau, et ce n'est qu'un mois après l'institution du traitement chez cette première malade que plusieurs auteurs anglais, MM Fox, Mackenzie, Baber et Lundie, commencerent leurs expériences."

It would appear, therefore, that the same idea occurred to four different physicians at about the same time. Such coincidences are not uncommon in the history of science. *Percent qui ante nos nostra dixerunt*—I am, etc.,

October 31st

THE WRITER OF THE ANNOTATION

MEDICAL WOMEN IN MEDIEVAL TIMES

SIR,—In your issue of October 31st (p 819) Dr Cullen raises points concerning Hildegard. I have set forth most of what I know of her in a long article on "The Scientific Views and Visions of St Hildegard" in the first series of my *Studies in the History and Method of Science* (Oxford, 1917). The article is based on a study of the manuscripts.

The *leta inquisitionis de virtutibus et miraculis sanctae Hildegardis* are printed in the *leta sanctorum Bollanda-na*, vol 1, p 697, and are conveniently accessible in Migne's *Patrologia Latina*, vol 197, column 131. I have personally formed a higher opinion of her virtues than of her miracles.

The record of Hildegard's life seems to me to reveal her as an erring and human woman, who was very far from being a saint, in any intelligible sense of the word. I cannot here discuss her failings of tongue, temper, and feeling, and I draw the veil over the treatment of the Albigenses (Cathari) for which she was in some part responsible. Yet despite her faults she was a fine and fiery spirit, and an exceedingly able and courageous woman. At her best she was humane, less intolerant, and more broad-minded than many leaders of her day. I am unmoved in my judgement by the cult of her by the good folk of Mainz, to which Dr Cullen refers.

As to her views, it is no charge of mine to determine what is orthodox. Nevertheless, it is my opinion, as an historical student, that doctrines voiced by her, notably her conception of Nature, are opposed to recognized Christian teaching. I would add that it seems to me improbable that Hildegard was conscious of the aberrant character of these views. Perhaps some who have written in her praise would be not a little perturbed if they realized what those views were. But that is another story. To follow it further would lead to a discussion of topics which cannot and should not be admitted to your hospitable columns—I am, etc.,

London, W C Oct 31st

CHARLES SINGER

SIR,—It is difficult within the four corners of a letter to reply fully to Dr C Singer's criticisms (October 17th, p 721) of my brief note in your JOURNAL on the medical school of Salerno and St Hildegard. Foundation for every statement in my letter is to be found in the following works of James Walsh, M D, LL D, Professor of History of Medicine, Fordham University School of Medicine, New York. *Education How Old the New*, 1911, pp 213, 214, 216, 219, *The World's Debt to the Catholic Church*, 1924, pp 149, 150, 152, *The Popes and Science*, 1911, p 226, etc.

Salerno, according to Dr Singer, was not a university in our sense. Sir D'Acié Power, in a foreword to *Magistri Salernitani nondum cogniti* (P. Cappaioni, Research Studies in Medical History, No 2), writes as follows:

"It is never easy to elucidate the early history of a corporate body which has existed for many centuries. What was true of the guilds was equally true of the universities and of the great teaching schools. Many of the most famous, like Salerno, Paris, Oxford and Cambridge began as voluntary assemblies of masters and pupils. The works of De Renzi and Gracchi [the historians of the school of Salerno] show that its origin was far different [from the fable of the meeting of Greek, Arab, Latin, and Jew] that it began in the Benedictine and Basilian Monasteries."

Dr P Cappaioni (*Magistri Salernitani*, already noted, p 17) says "At the end of the twelfth century great changes took place. We remark the establishment of a Guild of Doctors and of a Schola Medicorum, or *Universitas*, with statutes and chiefs of its own." Rashdall (vol 1, p 6 et seq) shows that "in medieval times the word 'university' means only an aggregate of persons, at the end of the twelfth century the words applied to a corporation of masters or of students. The term which most nearly corresponds to the vague and indefinite English notion of a university is not 'universitas' but 'studium generale,'" and on page 21, vol 1, he speaks of Salerno as "one great Studium Generale."

Further, as to the part the Benedictines played in the origin of the Salerno school, U Benigni, Professor of Ecclesiastical History, Pontificio Collegio Urbano di Propaganda, Rome, in the *Catholic Encyclopedia*, says "the origin of the Medical School of Salerno is to be found in a Benedictine monastery of Salerno established 794." Paekard's *History of the School of Salerno* (London, 1922, p 12) states "The monks [that is, the Benedictines] established monasteries in the city, and many authorities consider that the organization of the Medical School of Salerno on a scholastic basis was chiefly attributable to their activities." Dr Max Neuburger (*Hist of Med*, vol 11, Part 1, 1925, p 23), speaking of the foundation of the Salerno school, says "No doubt the Benedictines were indirectly of great assistance to its first rise."

Dr Singer says there were no professors at Salerno. Rashdall (vol 1, p 21), says the "three titles, master, doctor, professor, were in the Middle Ages absolutely identical."

Dr P. Capparoni, in his *Magistri Salernitani nondum cogniti*, adds, as the title of his book indicates, many new names to the list of masters (or professors) of the school of Salerno.

'None of the teachers can be shown to have been women,' and 'There is no evidence that women were 'admitted' to the 'university' in the twelfth century'—so states Dr Singer Rashdall (*Universities of Europe*, vol. 1, p. 86) states "Among the medical practitioners, teachers, and visitors of its primeval days were several women." Dr Capparoni, in his *Magistri Salernitani* (1923, p. 21), in a list of doctors in the twelfth century, mentions 'Beidefolia, Medica,' and says there is 'nothing foolish in supposing she was a lady doctor.' Prekard (op. cit., p. 17) states "There were other women besides who practised medicine and wrote on medical subjects at Salerno in the fifteenth century." Constanza received the degree of Doctor of Medicine. Women were undoubtedly admitted to the medical course at Salerno and received degrees and licence to practise." Also compare Dr Max Neubinger, *Hist. of Med.*, vol. II, p. 1, p. 25, footnote. The "Mulieres Salernitanæ," frequently quoted by Salernitan authors on account of their wide knowledge, particularly in matters of gynecology and cosmetics, were truly genuine women doctors, and it was no unusual thing for wives or daughters of the direction of the "Collegium" to become teachers. Dr Matheson Cullen's letter (October 31st, p. 819) makes further reference to St Hildegard unnecessary for me.

Dr Singer's reference to "ungrounded statements or untenable conclusions on medico-historical topics carelessly thrown off," and "wild and undocumented statements buried about," must be my apology for this lengthy letter. May I suggest that Dr Singer should add to his words "no evidence"—so frequently occurring in his letter—the words "satisfactory to me"? Then we might agree to differ—I am, etc.,

London S.W.1 Oct 30th

REYNOLD ROCHER

** We cannot continue this correspondence

THE TEACHING OF PHYSICAL TRAINING

SIR,—May I be allowed to reply briefly to the two letters in the *BRITISH MEDICAL JOURNAL* of October 24th (p. 769)?

In my article of October 3rd (p. 608) I pointed out the futility of doing a leg exercise after heavy exercise. Dr Timberg agrees that "no sensible person" would advocate such a thing. Yet those connected with the Swedish system of physical training know that leg exercises have been recommended by some of its disciples, "after violent effort such as running 'all out' in long-distance races, and after severe strain in prolonged tugs-of-war," also after running, etc., and that this teaching is widespread. Dr Timberg agrees with me that this is a mistake.

The leg exercise after heavy exercise is now abandoned in the Royal Navy. Movements of the arms during breathing exercises are also abandoned. When I began the work of physical training, seventeen years ago, these exercises were in vogue, being part of a Swedish system. Since then my own observations and the rapid advances in physiology have necessitated these changes. The effect of the leg exercises which have been retained and their proper application, also the physiology of both leg and breathing exercises, are fully discussed in my papers, which are being published in the *Journal of the R.N. Medical Services* in January next (obtainable from the Admiralty).

The other points raised by Dr Timberg, and also those by Major Austin, are already fully dealt with in the above-mentioned papers. I regret that I am unable to answer here more fully owing to the length of reply which would be required.

As regards the spine, excess of zeal, especially on the part of non-medical instructors in attempting to "straighten out the curves" leads to exaggeration of description and diagrams, even to the extent of showing a spine as straight as a ramrod and devoid of every vestige of curve. This exaggeration leads to exaggeration in exercises.

As a case in point I might refer to an exercise in which direct force is applied to the spine, with the purpose of

bending the dorsal curvature, which I have seen in a manual of physical training. Such exercises should not be applied to classes of human beings during physical training, and semi-medical exercises of the nature of breathing exercises and leg exercises found not to produce the effects ascribed to them should be eliminated from the curriculum. Normal spines should be left alone and not tampered with by non-medical physical training instructors. Faulty spines require medical treatment.

It is not advisable to call constantly the attention of a pupil to his heart or breathing. The centres for these functions have worked for so many ages that they are capable of working best by themselves, and only need to be left alone, especially by the uninitiated.

In physical training, leg exercises after heavy exercise should be omitted. Breathing should be done naturally with no arm movements. The normal curves of the spine should not be tampered with.

These points and their physiology are fully discussed in the papers mentioned above—I am, etc.,

Southsea Oct 26th

HORACE B. HILL

VENERAL DISEASE IN THE NAVY

SIR—The letter in your issue of October 31st (p. 819) from a retired naval medical officer condemns (unheard) the Admiralty for ceasing to include in the prophylactic outfit a silver preparation for the prevention of gonorrhoea, and he attributes to "departmental economy" the "resulting increase of gonorrhoea on such stations where alternative methods are difficult of application." By "alternative methods" is meant, I suppose, the early application of skilled disinfection in a disinfecting chamber on board and on shore.

It would appear that prophylactic outfits can be improved so as to diminish the incidence of gonorrhoea and that in certain stations the providing of convenient disinfecting chambers would further tend to reduce venereal disease in the navy. Until such improvement and provision is brought about a share of responsibility for the shamefully high figures for gonorrhoea in the Royal Navy is rightly to be attributed to inertia on the part of naval medical officers.

Once the disease has been required treatment in naval hospitals would be altogether admirable were it continued until every case was non-infectious. What my original letter (October 3rd, p. 629) protested against was the practice of discharging from the service incurable cases of gonorrhoea before sufficient time had elapsed to make certain that these were not a source of danger to the health of the civil community. It is deplorable that the Admiralty has not shared in the general enlightenment of the fact that has taken place since the Royal Commission on Venereal Diseases issued its report nine years ago. The Admiralty still fails to carry out the Commission's recommendation that men in the navy suffering from venereal disease should be detained until non-infectious—I am, etc.,

ROBERT FORCEN, M.D.

Janakshree Joint Committee on
Venereal Disease

Glasgow Oct 31st

The Services

TERRITORIAL DECORATION

THE Territorial Decoration has been conferred upon the following officers of the R.A.M.C. T.A. under the terms of the Royal Warrant of October 13th 1920: Lieut. Colonels C. H. Stannett, Redmond, and E. Beverley, B.D.S.O., Majors Charles Corfield, William J. Harrison, and Alister F. Lee, M.C.

DEATHS IN THE SERVICES

Surgeon General Christopher Pearson, R.H.P. R.N. (ret.) died at the Royal Naval Hospital Chatham on October 24th, aged 78. He was the youngest son of the late John Pearson of Macroom, Co. Cork, and was educated at the Queen's University of Ireland where he graduated M.A. in 1875 and M.D. and M.Ch. in 1875. He entered the navy soon after, and attained the rank of Inspector General of Hospitals and Fleets in May 1908, the title of rank being changed in 1911 to Surgeon General. He retired in February 1912. He served in the Egyptian war of 1882 and as surgeon of HMS *Invincible* took part in the bombardment of Alexandria, receiving the Egyptian medal with clasp and the Khedive's bronze star. From 1909 to 1912 he was Inspector General at Chatham. He was appointed honorary physician to the King on October 1st 1912. He was unmarried.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

THE Special Board for Medicine has appointed Dr L Cobbett Sir F G Hoplins, and Mr G L Wherry as members of the M.D. Degree Committee for the present academic year. Professor H R Dean M.D. has been elected to fill one of the two vacancies on the Council of the University Senate.

At a congregation held on October 30th the following medical degrees were conferred:

M.D.—G H Oriel
M.B. B.Chir.—J H Francis R Cove Smith H J H Hendley
L C Walker J A W Robertson
M.B.—J Russell

ROYAL COLLEGE OF PHYSICIANS OF LONDON

An ordinary quarterly committee of the Royal College of Physicians of London was held on October 29th, at 5 p.m., when the President, Sir Humphry Rolleston, Bt., was in the chair.

Members

The following candidates were admitted Members, having passed the necessary examinations:

Wm Fielding Addey M.B. Harold Gilbey Anderson M.B. Tudor Nath Bandgopadhyay M.B. Ambuj Nath Bose M.B. M.S. Reginald Thomas Brain M.B. Worthington E W C Routersz
* Under the Medical Act 1876

Dr J A Nixon of Bristol was appointed an Examiner in Medicine to serve until July 1927 in the place of Dr J W Russell (Birmingham) deceased.

A report was received from the President of the College who had attended the International Prison Congress as delegate.

The alterations in the by laws relating to the examinations for the Membership were read a second time and passed. Copies of the revised regulations can be obtained from the Registrar and a general indication of the changes will be found in a paragraph printed in the JOURNAL this week at page 860.

A letter from Dr Daniel O Connell Dunigan asking that the Membership which he resigned in 1912 might be restored to him, was read a second time. The application was granted.

Dr R A Young was re-elected a member of the committee of management and a report of a formal nature was received from the committee.

The President announced the award of the Streetfield Scholarship to Norman Leslie Capener, F.R.C.S. whose subject of research is "The comparative anatomy and function of the prostate gland", of the Jenks Scholarship for 1925 to Oliver Iye, of Guy's Hospital Medical School and formerly of Epsom College, and, by the University of Edinburgh, of the Murchison Scholarship for 1925 to Miss Sidney Elizabeth Gloskery.

After some other College business of formal character, the President dissolved the committee.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At the annual meeting of Fellows and Members to be held at the College on Thursday, November 19th, at 3 p.m., a resolution will be moved on behalf of the Society of Members of the Royal College of Surgeons of England reaffirming the desirability of admitting Members to direct representation upon the Council of the College, and requesting the Council (now about to apply to the Privy Council for a supplementary charter) to avail itself of this opportunity to insert a provision therein for some representation of Members, as such, upon the Council. The resolution will be moved by Dr L Haden Guest, M.P., and supported by Dr J O'Donovan, Mr M J Smyth, F.R.C.S., and Mr F Lawson Dodd.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY—R F Ashkeny A G Dreosti O L Froehlich E J Now man M Pettigrew M V Roberts G E Rowan P B Skeels J Tarshish M E G Wilkinson H J F Wood
MEDICINE—M Bannounah A O Dreosti A M El Misbad A L Evans C L Froehlich T H Harrison M Hook N H Ibrahim I G Martin P B P Mellews E J Newman L H Rampling F Reynolds L A Rostant G H Shanley J Tarshish

The diploma of the Society has been granted to Messrs J H Clapp S W Cuff A O Dreosti A L Evans, T H Harrison, E P Hyde, N H Ibrahim, I J Neyman F Reynolds, M V Roberts G H Shanley, P B Skeels M L G Williamson, F Winelake, H J F Wood.

Obituary

GEORGE HAYNES FOSBROKE, M.R.C.S., D.P.H.,

County Medical Officer of Health for Worcestershire

WE regret to announce the death, on October 27th, of Dr G H Fosbroke, at the age of 75, after an illness lasting nearly a year. He died in the house at Bidford-on-Avon in which he himself, his father, and his grandfather had been born.

George Haynes Fosbroke received his medical education at the Westminster Hospital, and obtained the L.S.A. in 1871, the M.R.C.S. Eng. diploma in 1872, and the D.P.H. Camb. in 1875. During his student days he served as a surgeon's assistant in the Franco-German war, and subsequently received the French war medal. The Royal Commission at the end of 1871 led to the establishment of a public health service, the old Poor Law being superseded by the new Local Government Board, medical officers of health were appointed for different parts of the country, and in 1873, after holding house appointments at the Westminster Hospital, Dr Fosbroke was appointed whole-time medical officer of health to the combined rural and urban districts of Stratford-on-Avon, Licham, and Alcester. In 1890 he was appointed the first medical officer for the Worcestershire County Council, and, at his death, he was the last surviving county medical officer of those who were originally appointed when these posts were first created. His duties were extended in 1906 by his appointment as chief medical officer to the Worcestershire Education Committee. Dr Fosbroke published articles in the BRITISH MEDICAL JOURNAL and elsewhere on cancer, the etiology of diphtheria, copper poisoning, the Midwives Act, and on sanitary matters generally. He was summoned as an expert witness before the Royal Commissions on physical deterioration and the metropolitan water supply. He was a Fellow of the Society of Medical Officers of Health, and a member of the Epidemiological Society. He leaves no children, and so ends one of the first branches of

an English country family whose members for nearly 600 years have remained close to their original home

For the following appreciation we are indebted to Dr MIDDLETON MARTIN, County M.O.H. for Gloucestershire

Comparatively young as is the public health service, the time has arrived when it must be expected that the pioneers will have finished their allotted task. Yet when the death of one of them is reported deep regret is felt and the loss of Dr G. H. Fosbrooke is by no means the least of those which we now have to deplore. Evidently in his early days he was impressed with the possibilities of preventive medicine, for he was one of the very small number of whole-time officers appointed in 1873 for groups of sanitary districts, which included the late Dr Francis Bond, in the neighbouring county of Gloucestershire. Dr Fosbrooke's determination to equip himself fully for his life's work is shown by the fact that in 1875 he sat for the first examination held at Cambridge University for the diploma in public health. The esteem felt for him by his medical colleagues was indicated by his election in 1881 as president of the Birmingham and Midland Association of Medical Officers of Health, which became a branch of the parent society in 1888. There can be little doubt that it was largely as a result of his work and influence that the Worcestershire County Council was one of the first to take advantage of the permissive powers granted by the Local Government Act of 1888 to appoint county medical officers of health; this decision was not reached without considerable opposition, meetings of protest being held in a great number of places in the county. The final result was that the Worcestershire County Council was fortunate enough to secure the services of Dr Fosbrooke as county medical officer of health in 1890, and with his assistance it became one of the most progressive authorities in promoting public health measures; this appointment he held for thirty-five years. Not only was he successful and happy in his own branch of work, but he had the capacity, not usually possessed by whole-time medical officers of health in those days of maintaining friendly relations with his colleagues in general practice. This was demonstrated particularly by his election to the presidency of the Worcestershire and Herefordshire Branch of the British Medical Association in 1894. Dr Fosbrooke's public health work was not restricted to Worcestershire; he acted as adviser to the Gloucestershire County Council from 1900 to 1902, and summarized the public health reports for those years. He was also the representative of the Local Government Board on the London Sanitary Inspectors' Examination Board, and was an examiner for the Royal Sanitary Institute. In 1902 he was largely instrumental in founding the Knightwick Sanatorium for Tuberculosis, which, starting with sixteen beds, became, in 1915, the King Edward VII County Memorial Sanatorium, with eighty-six beds. Of him it may be said generally that there are few men in the public health service who have been more successful in promoting the true aims of preventive medicine, and this in a quiet, unassuming manner which overcame prejudice and encouraged the local authorities of Worcestershire to establish numerous works of water supply and sewerage to the advantage of the population of to-day and of generations to come. While these constructional works will long remain to be memorials of his public health activity, Dr Fosbrooke realized that preventive medicine had a far wider scope, and in few counties is there a more lively public health atmosphere than that which he was successful in generating in Worcestershire. As a man there were few more welcome in any sphere of life for Dr Fosbrooke was a sportsman in the best sense of the word. This was shown by his form of recreation, which was open-air sport, from boyhood to the time of a hunting accident he was a well-known follower of three packs of foxhounds and from 1876 to 1883 he was master and huntsman of the Bidford-on-Avon hounds. Inappreciated for this sport by his resident, game shooting took its place, and instead of a prolonged annual holiday, days spent in shooting—perhaps the better form of recreation—gave him the change he needed from official work. To younger men in the service he was particularly kind, and many owe him a deep debt of gratitude for his generous help and encouragement.

The deaths of the following foreign members of the profession have recently been announced: Dr I. Schwartz, honorary surgeon to the Paris hospitals and member of the Académie de Médecine, Dr Richard, professor of pharmacology and materia medica in the Paris faculty of medicine, Dr Ranvier, president of the Belgian Royal Academy of Medicine, and professor at the University of Louvain, Dr Victor Jacques, honorary professor in the Brussels faculty of medicine, where he had successively lectured on physiology, therapeutics, and pharmacy (aged 72). Professor John Addison Fordyce, well-known dermatologist of New York (aged 67). Dr Karl Schlosser, professor of ophthalmology at Munich (aged 68). Dr Juan Cisneros Sevilla, professor of otolaryngology in the Madrid faculty of medicine since 1902, and member of the Spanish Royal Academy of Medicine. Dr Anton Bum for many years editor of the *Wiener medizinische Presse* and of the *Wiener Anzeiger* (aged 69), whose book on massage and therapeutic gymnastics passed through several editions.

Medical News.

A SERIES of four lectures on the history of medicine will be given at University College Hospital Medical School by Dr Charles Singer. The first lecture, on Thursday, November 12th, at 4.15 p.m., will be on influenza, the succeeding lectures, which will be given on the same day of the week and at the same hour, will be on diphtheria, enteric fever, and small pox.

THE next meeting of the Dental Board of the United Kingdom will be held at 44, Hallam Street, W.1, on Tuesday, November 10th, at 2 p.m., when the chairman will deliver an address and the Board will consider disciplinary and other business.

THE fifth of the present series of lectures arranged by the Fellowship of Medicine will be delivered by Dr F. J. Poynton, on some points in the diagnosis of tuberculosis in the child on Monday, November 9th, at 5.30 p.m., in the lecture hall of the Medical Society of London, 11, Chandos Street. All members of the medical profession are welcome. Special courses now in progress are gynaecology at the Chelsea Hospital for Women and venereal diseases at the London Lock Hospital. Dr Porter Phillips and Dr Thomas Beaton began a series of eight lecture demonstrations on psychological medicine at the Bethlem Royal Hospital on November 3rd. At the Victoria Park Hospital a two weeks course in diseases of the chest has been arranged from November 9th to 21st. From November 23rd to December 12th the Royal Waterloo Hospital will hold a course in medicine, surgery, and gynaecology. For the convenience of general practitioners the London Temperance Hospital will give a five afternoon course in general subjects (4.30 to 6 p.m.) from November 23rd to December 4th. A course on diagnosis and treatment of nervous diseases will take place at the West End Hospital (73, Welbeck Street) from November 23rd to December 12th. Copies of each syllabus, and also the general course programme, may be obtained from the Secretary to the Fellowship at 1, Wimpole Street, W.1.

THE Huxley memorial lecture before the Royal Anthropological Institute will be given this year by Sir Arthur J. Evans, F.R.S., at the rooms of the Royal Society, Burlington House, W., on Tuesday, November 24th, at 8.30 p.m. The subject will be early Nilotic, Libyan, and Egyptian relations with Minoan Crete.

THE next meeting of the Royal Commission on Lunacy and Mental Disorder will take place at 1, Whitehall Gardens, S.W., on Tuesday, November 10th, at 10.30 a.m.

SIR DAVID PRAIN, F.R.S., formerly director of Kew Gardens, who before he held that office was director of the Botanical Survey of India, will give a lecture on some useful plants of India at an evening meeting of the Pharmaceutical Society of Great Britain, to be held at the society's house (17, Bloomsbury Square, W.C.1) on Tuesday next, November 10th, at 8 o'clock.

A SHORT course of lectures on functional nerve disorder has been arranged at the Tavistock Clinic for Functional Nerve Cases, 51, Tavistock Square, W.C.1. The course will include six lectures by Dr J. R. Rees on the psychological factor in general practice, to be given on November 16th, 17th, 18th, 23rd, 24th and 25th at 4.30 p.m. Four lectures on the endocrines and general metabolism in the psychoneuroses by Dr W. Langdon Brown on November 19th, 20th, 26th, and 27th, at 4.30 p.m., and ten lectures by Dr H. Crichton Miller on the theory and causation of the psychoneuroses,

to be given daily at 5.30 p.m. from November 16th to 20th and November 23rd to 27th. The fees for the combined course are for medical practitioners £2 2s., and for medical students 10s. 6d.

THE International Society of Medical Hygiene will hold, in conjunction with the Section of Bacteriology and Climatology of the Royal Society of Medicine, a special meeting in the Barnes Hall of the Royal Society of Medicine, 1, Wimpole Street, W. 1, on Friday, November 27th, at 10 a.m., to discuss the treatment of rheumatism in industry. The president of the International Society, Dr. Gustave Monod (France), will take the chair, and among those expected to take part in the discussion are Sir George Newman, chief medical officer to the Ministry of Health, Dr. Van Bredon (director of the Institute for Physical Treatment, Amsterdam), Dr. Kern Pinnle (Harrogate), Dr. F. Konmann (Switzerland), Dr. Buckley (Bristol), Dr. Kahlmeter (Consultant to the Pensioners Department, Stockholm), Dr. Louis Blanc (France), Dr. Schmidt (Czechoslovakia), and Drs. Otto May, Llewellyn, Ray, and Fortescue Fox.

At a meeting of the Dutch Section of the International Society of the History of Medicine at Gorinchem on October 18th, in connection with the congress to be held at Leyden in 1927, an executive committee was formed with Dr. J. G. de Lint of the Hague as president, and Drs. J. E. Kroon of Leyden and J. B. I. van Gils of the Hague as secretaries.

THE annual Sheffield medical dinner will be held in the Royal Victoria Hotel at 7.30 p.m. on Thursday, November 12th. Applications for tickets (12s. 6d.) should be made to the Honorary Secretary, Dr. J. Eric Stacey, 2, Durham Road, Sheffield.

THE Aberdeen University Club, London, will hold its biannual dinner at the Criterion Restaurant, Piccadilly, at 7.30 p.m., on Thursday, November 19th. Professor H. M. Macdonald will be in the chair, and the guest of the evening will be Sir Humphry Rolleston Bt., President of the Royal College of Physicians of London. Any graduate, past or present, wishing to attend the dinner or join the club should communicate with Dr. Milhigan, 11, Upper Brook Street, W. 1.

THE Royal Dental Hospital School of Dental Surgery will give in "At Home," which medical men are invited to attend, at the hospital (32, Leicester Square, W. 2) on Saturday, November 21st, from 2 to 5 p.m. The annual dinner of the staff will take place the same evening.

THE annual dinner of the British Serbian Units Branch of the British Legion will be held on December 10th, with Sir James Purves Stewart, K.C.M.G., M.D., in the chair. All who worked for the Serbians and their friends are invited. Tickets, price 7s. 6d., may be obtained from Mr. H. B. Ives, Oxford House, Junction Road, N. 19.

DR. FRANCIS HARD asks us to correct the announcement, supplied to us by the Norwood Sanatorium, Limited, and published last week (p. 821). He has, he says, resigned his connexion with the Norwood Sanatorium, not owing to ill health, for his health is excellent, but only that he may open a similar institution at Chislehurst.

DR. W. JAMES SUSMAN has been unanimously adopted as Mayor for the borough of Henley on Thames for the ensuing year.

THE appointment of Sir William Job Collins, K.C.V.O., to be Vice-Lieutenant of the County of London has been approved by the King.

DR. JAMES FERGUSON LEES, Director-General of Public Health Ministry of Interior of the Government of Egypt, has been granted by the King licence and authority to wear the insignia of the second class of the Order of Ismail conferred upon him by the King of Egypt in recognition of valuable services rendered.

THE Sanitation supplements of the *Tropical Diseases Bulletin* ended with the issue of October 30th. It is announced that the publication of a monthly *Bulletin of Hygiene* will begin in January, 1926; this periodical will review the literature of public health and preventive medicine of the English speaking world, the annual subscription will be 21s., post free, payable in advance to the Tropical Diseases Bureau, 23, Endsleigh Gardens, N. W. 1.

A RECENT report issued by the Nobel Prize Committee arranges in the following order the countries which have been recipients of the prize from 1921 to 1924: Germany 26 times, France 21, Great Britain 14, America 9, Sweden 7, Denmark and Holland 6 times each, Switzerland 5, Austria, Belgium, Norway, and Italy 4 times each, Spain 3, Poland 2, Russia and India once.

WE have received the first issue, dated October 1st, of *Forschungen und Fortschritte*, a fortnightly journal published in Berlin, which is to be devoted to recent progress in German science and technique, including the relations of German science with that of other countries.

THE Tokyo municipality has decided to build six new hospitals with isolation wards for infectious cases, since at present considerable delay occurs in the transfer of these patients to the only isolation hospital existing in Tokyo. All the buildings will be reinforced concrete, three stories high, with a basement, and with gardens on the roofs. It is proposed to establish three new hospitals in Tokyo and elsewhere for the benefit of employees in the department of communications. The temporary building to replace the Yokohama General Hospital, which was destroyed in the earthquake of 1923, has been completed, and the hospital committee hopes to have sufficient funds in hand by the end of the year to begin the reconstruction of the permanent building.

THE Moscow Public Health Office has recently issued a German version of a report for the six months October, 1924, to March, 1925. This contains a brief survey of its activities, which include the establishment of dispensaries and sanatoriums for combating tuberculosis, venereal diseases, and drug taking, the inauguration of infant welfare centres and maternity homes, the improvement of workmen's dwellings, the prevention and treatment of the common infectious diseases, especially scarlet fever, diphtheria, and malaria, and the provision of sanatoriums for tuberculosis.

MESSRS. W. HEFFER AND SONS, LTD., Cambridge, announce for early publication *The Nature of Tumour Formation: The Erasmus Wilson Lectures, 1925*, by Dr. W. G. Nicholson, reader in morbid histology in the University of London, and lecturer in clinical microscopy, Guy's Hospital Medical School.

PROFESSOR KARL JOSEPH LEBERT, who discovered the typhoid bacillus in 1880, has recently celebrated his 90th birthday.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W. C. 1**.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their article published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W. C. 1, on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal* should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are: *MUSEUM* 9361 9362 9363, and 9364 (internal exchange four lines).

THE TELEGRAPHIC ADDRESSES are: EDITOR of the *British Medical Journal*, *Antology Westcent, London*.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements etc.) *Articulate Westcent London*.

MEDICAL SECRETARY *Mediscra Westcent London*.

The address of the Irish Office of the *British Medical Association* is 16 South Frederick Street, Dublin (telegram: *Bacillus Dublin* telephone 4737 Dublin) and of the Scottish Office 6 Drumsburgh Gardens, Edinburgh (telegram: *Associate, Edinburgh* telephone 4361 Central).

QUERIES AND ANSWERS

THE PROPHYLACTIC VALUE OF QUININE IN MALARIA

"G. M." writes: It has been stated by different observers that quinine is of no value as a preventive of malaria, its failure being attributed in some cases to the relative insolubility of the tablets used. I should be glad to know whether quinine is still generally accepted as a prophylactic and if so what is the most suitable preparation and what the dosage to employ.

.. The statement that quinine is of no value as a preventive of malaria is largely based on experimental work—that sporozoites are not destroyed by the drug. In practice however it is found efficacious and a vast majority of old residents in the tropics vouch for this. It is true that tablets can be hammered without being broken and that they can also be collected from the faeces unaffected by passage through the alimentary canal. This is due to the coating of sugar, stearates etc., which becomes very hard in the tropics. For effective prophylaxis the quinine must obviously be taken in an absorbable form as liquid or powder or if in tablets these should be uncoated and not too compressed. Five grains daily is the dose usually employed and, though some take only two grains the former is safer. The bishydrochloride, being the most soluble, is the best salt to use.

INCOME TAX

War Pensions

"X" is in receipt of a civil pension, having been invalided from the Gold Coast service. His retirement was caused or at least accelerated, by haemorrhoids developed as a result of dysentery contracted whilst serving on the medical staff in the Cameroons during the war. Is he chargeable to income tax in respect of the pension?

* * The exemption which "X" has in mind applies to wounds and disability pensions granted to members of the naval, military, or air forces of the Crown, or retired pay of disabled officers granted on account of medical unfitness attributable to or aggravated by naval etc., service. It is, we think, fairly clear from the section (Section 16 of the Finance Act, 1919) as a whole that it deals only with pensions, etc., given for military etc. service and not with civil pensions, even though, as in

"X's" case their early receipt and consequently the reduction in the pensioner's income is referable to similar causes. We fear that he has no claim to exemption in respect of his pension.

Division of Partnership Assessment

J. D. F. puts the following query: A, B, and C are partners in a medical practice. A proposes to retire from the practice on June 30th 1926. Owing to a change in partnership some years ago the books of the firm were made up on June 30th in each year and the assessment of the firm for the income tax year 1926-27 has already been agreed to with the inspector of taxes as under:

Profit for year ended June 30th 1923	£
1924	4 408
1925	2 887
	2 752
	310 017
	£3 349

Assessment for 1926-27

Our correspondent asks: What is A's liability in respect of the profits of the firm up to June 30th 1926 and what is the usual procedure in these cases?

* * The tax payable in July 1926 will relate to the assessment for the year to April, 1926 and therefore will not be affected by the change. The tax so affected will be that payable January and July 1927, in respect of the assessment for the year to April, 1927. The statutory rule is laid down by Section 20 of the Finance Act 1918, and provides that the income of a partner shall be deemed to be the share to which he is entitled during the year to which the claim relates etc. Consequently (assuming A, B, and C to be entitled to the profits in equal shares) A's share of the 1926-27 gross assessment will be one third for one quarter of the year—that is one twelfth of the whole or £279 and from this he will be entitled to the usual allowances and reliefs. If he is a married man, for instance his net liability would be £279-£225=£54 at half the standard rate of tax less any life assurance and other reliefs to which he may be entitled. If there should be any tax payable by him for 1926-27 it may be convenient for him to pay (by arrangement with his partners) the whole of his share as part of the January instalment, thereby obviating the trouble of making a small payment in the following July.

LETTERS, NOTES, ETC.

COCKROACHES

We have received a number of replies to the inquiry as to how to rid a country hospital of cockroaches. They may be summarized as follows:

"F" tells us that he quickly got rid of cockroaches which overrun his house by acting on the following advice: Mix 1 part powdered borax with 4 parts of sugar. Place a little heap of this heap and there near the runs of the cockroaches. See no crumb or remains of food are left about.

Dr F. C. Forster (Bournemouth) recommends Scott's beetle exterminator made by Messrs A. Scott and Co. 244 Beresford Street London S.E. It can be obtained from any chemist. It is a powder and is sprinkled over floors especially in cracks and crevices, and along the skirting junctions of walls with the floors. Its use must be resisted with Dr Forster wishes it to be understood that he has no interest in the firm mentioned.

"M.B." recommends either "Blattis" sold by Messrs Howarth 473 Cooke's Moor Road Sheffield or "Magnet" insect powder to be obtained from Messrs Boots.

An "M.O.H." recommends "Rydene," a proprietary substance manufactured by Messrs Rydene Ltd 115 High Holborn, W.C. It is cheap, non-corrosive and non-inflammable. It is not to be recommended for bugs as it has not the penetrative power of the petrol containing mixtures but for vermin in clothing and for cockroaches it is he says excellent. For bugs "Solution D" (also a proprietary substance) gives he finds good results: cylinder 1/2 pint water 5 pints) used as a spray is efficacious, both for bugs and cockroaches. It is not inflammable, both these substances are expensive however.

Dr D. A. McCurdy (Londonderry) advises the inquirer to employ a plumber to go round the places where cockroaches congregate thoroughly treating each area with the flame of a blow lamp.

Messrs. ARNOLD AND SONS (John Pell and Croxden, Ltd) 50, Wigmore Street London W.1, write to recommend 'Boli No' liquid. It is used as a spray.

Messrs. HAYMOND inform us that they sell a liquid preparation, "Pestelin," which is used as a spray. It is effective, they say, against flies and moths as well as beetles.

TREATMENT OF DEAFNESS AND TINNITUS

Dr F. G. CANNON (Durban) writes: May I suggest that more consideration be paid to the possible removal of the upper wisdom teeth, cauterization of the inferior turbinate bodies, and the avoidance of congestion of the middle turbinates by attention to the diet and by an early morning dose of sodium sulphate in those cases of chronic deafness and tinnitus where there is no obvious indication for the correction of nasal obstruction due to deflected septum or nasal spur or for the surgical treatment of a latent sinusitis. Many such cases are unlikely to respond to nasal douching with saline, and electrical methods are still on trial, while a gastric cause of the condition is sometimes overlooked. I have often found that a good deal of discomfort can be avoided at night by raising the posts of the bed on bricks at the head end of the bed, and am sure that a great deal of unnecessary suffering of patients who experience a severe reaction after local anaesthesia of the nasal passages can be avoided by this method of sleeping on a slope, instead of causing further healing of the head by the use of pillows.

FIAT AND LORD

Mr H. MASSIE BUIST writes: With reference to the statements cabled at intervals during the last four weeks by responsible news agencies from the United States of America and from the continent of Europe concerning an alleged agreement entered into between Fiat and Lord, Messrs Fiat (England) Ltd., now inform me that that information is without foundation. In reviewing the passenger car show at Olympia from the doctor's viewpoint I made tentative reference to the proposal apropos the new 7 h.p. Fiat chassis pointing out that without this insouciant, that production firm would still have a notable effect on the evolution of the small car during the next five years. Moreover, of course the above disclaimer does not in any way affect the current activities of American financiers and motor manufacturers to secure control of important British car building enterprises: the Vauxhall shareholders, for example, having accepted the proposals put forward on behalf of General Motors at an extraordinary general meeting on October 30th, at which there were, however, some dissentients.

ULTRA VIOLET RADIATION

We have received from Messrs Watson and Sons (Electro Medical), Ltd (Fisher Street, Kingsway, W.C.) a pamphlet entitled *Artificial Sunlight*. In a few pages it gives a sketch of the history of the therapeutic application of ultra violet radiation without however lending itself to the exaggerated claims which have lately been prevalent in some sections of the lay press and then it goes on to discuss the comparative value of the different types of lamps for general or local irradiation. The remainder of the pamphlet is an illustrated catalogue in which seventeen models of lamps are described including various arrangements for utilizing mercury vapour tungsten, and carbon arc sources and, for low intensities metal filament lamps in quartz. The pamphlet slight as it is gives a comprehensive picture of the range of instrumentation now available in photo therapy. For the general practitioner the tungsten arc is recommended by the producers of the pamphlet as the source of greatest general utility, although special conditions might lead him to favour one of the other sources.

AN EXPLANATION

Dr JEFFREY WENTWORTH MALIM (St Marychurch Torquay) writes: In the *Daily Mail* of November 3rd is an account of an inquest on a medical practitioner calling himself Dr Jeffrey Wentworth Malim of South Kensington. I am Jeffrey Wentworth Malim and the dead man was not a doctor, or else was one using my name.

SMITH'S VISITING LIST

Smith's Physicians' and Surgeons' Visiting List is a neat and well made volume for the pocket which has been of service to generations of medical practitioners. Two varieties can be obtained in either cloth or leather binding; the one (No. 3) with space for seventy five patients and a journal for engagements and the other (No. 4) for 100 patients without the journal.

¹ *Smith's Physicians' and Surgeons' Visiting List for 1926* (Fiftyth year London: Hazell Watson and Viney Ltd 1925) (34x6 1/2) No. 3 cloth 7s 6d leather 10s 6d No. 4 cloth 10s leather 12s.)

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 43, 44, 45 and 48 of our advertisement columns and advertisements as to partnerships, assistantships, and locumtenencies at pages 46 and 47.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at pages 167 and 168.

British Medical Association.

PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, BATH, 1925

SECTION OF SURGERY.

SIR BERKELEY MOYNIHAN, Bt, KCMG, CB, MSc, FRCS, President

DISCUSSION ON CARCINOMA OF THE STOMACH

OPENING PAPERS

I—SIR WILLIAM I. DE COURCY WHEELER, MD, FRCSI, Past President RCSI

To emphasize the tragic importance of this subject to the community, I need only remind the meeting that there are about 10,000 deaths annually from cancer of the stomach in the British Isles. Looking back twenty-five years I can recollect, as a student, the orthodox teaching at the bedside the emphasis laid on the palpable tumour, on the coffee-ground vomiting, on the absence of hydrochloric acid, and when, by good fortune more than by good management, an early cancer of the stomach was found at operation, the discovery was usually followed by rapid closure of the abdomen. Except in the hands of a few surgeons gastrectomy was regarded as outside the bounds of justifiable surgery.

A great advance has been made. Efforts to ensure early diagnosis and efforts to perfect operative removal have gone hand in hand, and the results of a recent years operative technique has of diagnostic endeavour. To-day, in the absence of prevention, the early diagnosis of cancer of the stomach is the real problem on which all attention should be concentrated. Early diagnosis means safe operation and a reasonable chance of permanent cure.

DIAGNOSIS

I think perhaps a useful purpose will be served if my criticism of diagnostic methods is, in the first place, destructive, in this way attention will be focused on the fallacies which surround a large proportion of textbook teaching. It may be said at once that the symptom-complex of carcinoma of the stomach is so vague, and varies so considerably, that an early gastric cancer may escape detection although every path known to science has been explored in the search. Gastric analysis, for example, is one of the beaten tracks, but does not, of necessity, lead to any definite goal. In 1879 the absence of free hydrochloric acid in gastric carcinoma was noted, but we know now that it is present in over-abundance in cases where an ulcer is undergoing malignant degeneration. In the records of the Mayo Clinic it is stated that the absence of hydrochloric acid occurs in a little less than one-half the cases of carcinoma of the stomach, normal or hyperacid values may be expected in one-fourth. It is not too late to broadcast such findings, for, notwithstanding all the biochemical reports in connexion with cancer, there is still a wide belief that the presence of free hydrochloric acid excludes the likelihood of gastric cancer.

Peterson and others lay stress on the importance of complete fractional analysis in differentiating between such conditions as gastritis, gastric ulcer, hour-glass stomach, and carcinoma, but the broad fact remains that the diagnostic results obtained by any method of analysis of the gastric contents are not encouraging. Furthermore, free hydrochloric acid may be absent in many conditions which clinically simulate cancer of the stomach—viz, for example, pernicious anaemia, hour glass stomach, syphilis, actinomycosis, viscerosptosis, and wasting diseases in general. It is absent also in about 29.4 per cent of cases of simple gastric and duodenal ulcer. The presence of lactic acid and the absence of hydrochloric acid may be regarded as a straw of evidence to show which way the wind is blowing, but

such a finding is little or no aid towards early recognition. Some pin their faith to the presence or absence of occult blood in the faeces, but the tests contain too many fallacies to be of any real practical importance. The Salmon albumin test, the serum reactions of Kelling, and such like procedures, have not received wide approbation. Barnett Joseph sums up the situation well when he says that there is no specific diagnostic test, either chemical, microscopical, or serological, of any value in gastric cancer.

Probably the advent of accurate x-ray examinations represents the greatest advance in the diagnosis of gastric malignancy, but in admitting this we must be fair to the radiologists and not classify them amongst miracle mongers. If a malignant tumour involves all the coats of the gastric wall, the rays usually show a defect in the contour of the stomach, and a lack of peristalsis is visible in the involved portion, but if the carcinoma is small and has not yet infiltrated the muscular coats of the stomach, then neither defect in contour nor abnormality in peristalsis is of necessity evident. Cancer at the cardiac end of the stomach and cancer with a patulous pylorus may escape detection in the hands of the best radiologists. Negative findings, just as in the case of clinical investigation and gastric analysis, are of doubtful value, and the value of positive findings should not be too emphatically emphasized. Tumours of neighbouring organs pressing on, or adherent to, the stomach wall may produce a filling defect which closely simulates an intragastric lesion. I have no experience of the use of the gastroscope, nor, for that matter, of the oesophagoscope, and for this want of experience I am consoled by Sir John Bland-Sutton, who referred to the use of these instruments as requiring the instinct of a sword swallower and the eye of a hawk.

Some rare signs of early cancer of the stomach should be borne in mind. My colleague, Professor T. G. Moorhead, has drawn attention to venous thrombosis as an early sign of gastric cancer. Trousseau stated that if, when in doubt as to the nature of an affection of the stomach, one observed a vein to become inflamed in the arm or leg, all doubt may be dispelled and a positive diagnosis be made. This obliterative phlebitis is a recognized factor in cases of advanced cancerous cachexia, but it may be the earliest symptom of a latent carcinoma. Various explanations of the phenomenon have been given: enfeeblement of the circulation, changes in the blood, and terminal microbial infection have been mentioned.

The first of four cases mentioned in Dr Moorhead's paper illustrates what a valuable sign venous thrombosis may be in early gastric carcinoma. The patient to whom I refer, when apparently in good health, suddenly developed thrombosis of the internal jugular vein, which gradually extended into the axillary and innominate veins, with swelling of the right arm. Radiographical examination of the thorax was negative, as was the Wassermann test, and there was a normal count of both red and white blood cells. The patient had a good appetite, and for a few days the thrombosis appeared to be subsiding, but it then appeared on the opposite side of the neck, the left arm became affected, and death supervened. At the necropsy an unexpected but typical cancer of the lesser curvature of the stomach was found. The thrombi in the veins contained neither cancer cells nor other organisms. Goff, in 1894, described a case with symptoms of generalized phlebitis lasting eight months, without signs or symptoms of malignant disease. A non-ulcerative cancer of the lesser curvature was found after death. These cases belong to the rare group of latent cancer of the stomach with peripheral venous thrombosis as the earliest, and indeed the only prominent symptom throughout. I have always looked for, but never once found, the glands above the left clavicle enlarged; the point is mentioned so frequently as a diagnostic aid that I would like to hear the experience of others in this connection.

Exploration.—How is the goal of early diagnosis to be reached? In the majority of early cases, in which there is a strong suspicion that the patient is suffering from some gastric ailment not responsive to medical treatment, there is only one reliable means of making the diagnosis, and that is by exploration. William Mayo, in 1904, insisted upon this

point Exploration can be safely accomplished through a small incision, and with only a short time of disability. Ho writes as follows:

"It is said that the patient will not submit to an abdominal incision upon suspicion. Herein we do the intelligence of the public an injustice. We have seldom been refused the opportunity when the matter has been fairly and candidly laid before the patient and his friends. The plea for delay has more often come from the attending physicians."

I have for many years taught my students that if there is no gain of weight, or at least maintenance of weight, in a gastric case after efficient medical treatment, malignant disease should be suspected and exploration is more than justified. Sir Thomas Hordey told me that he suspected carcinoma and recommended laparotomy in a gastric case, irrespective of age, whenever there was a failure to gain weight or to maintain weight after the end of the third week of efficient medical treatment.

There is a small group of patients who seek advice the moment their health becomes impaired, and in whom early diagnosis is easy. In this lucky few the accumulation of evidence—clinical, biochemical, and radiographical—all points in the same direction, and a large percentage of such cases are cured by gastrectomy. In late cases diagnosis is easy but futile, adding only mental misery and despair to the physical suffering of the victim.

Anæmia—We are frequently confronted with the type of patient in which anæmia is the prominent feature, and it would be well to focus attention on this group by describing it as the "pernicious anæmia" type of cancer of the stomach. The differential diagnosis is often difficult. In pernicious anæmia the blood changes are not so characteristic as some would have us believe. Achlorhydria is always present, gastric stasis may or may not exist. In doubtful cases it is helpful to treat the patient with arsenic for about three weeks. In pernicious anæmia there is often temporary marked improvement, but in cancer of the stomach there is no improvement, and more often diarrhoea and nausea follow the administration of the drug. It is interesting in this connection to note the pernicious type of anæmia which follows complete gastrectomy.

Cancer in Young People—There has been too much said, I think, about the "cancer age." From time to time young people are admitted to hospital suffering from cancer of the stomach. Sullivan of New York mentions six cases below the age of 10 years, four cases in infants under 6 weeks, one in a child of 18 months, and thirteen cases in the second decade of life.

By thinking too much of the "cancer age" I missed the diagnosis of a fairly clear case of cancer of the stomach in a patient aged 20. He was admitted into Meigs's Hospital some years ago suffering from gastric symptoms before the time of routine bismuth meal examinations. At operation an extensive inoperable malignant growth of the stomach was found. With rigid medical treatment for over six months previously the course of his illness had continued progressively downhill, loss of weight and anæmia increasing in defiance of every therapeutic effort. At the moment I have a patient aged 30 in the last stages of gastric carcinoma.

In young people there is often an absence of cachexia, an early onset of high temperature, and rapid appearance of metastasis. These three special signs may be explained by the accelerated disintegration and breaking down of carcinomatous tissue which is to be expected in the early and active years of life.

Differential Diagnosis

It must be borne in mind that other pathological conditions may coexist with cancer of the stomach. In *Hamlet* we find—"There needs no ghost, my lord, to come from the grave to tell us this", and yet the obvious often escapes our attention.

I recall a case in which the diagnosis of early carcinoma of the cardiac end of the stomach was made by a medical colleague and radiologist friend on what seemed to be inconclusive evidence. I saw the patient in consultation, and detected a tumour in the left hypochondriac region. I felt certain, from its size, that the tumour was not a carcinoma

of the stomach, for all the evidence pointed to a very early growth. Further investigation brought me to the definite conclusion that the tumour was renal in origin, and that the filling defect shown by the x-rays was due to the tumour pressing on, or being adherent to, the stomach wall. On opening the abdomen a solitary cyst of the left kidney was found, but on passing the hand upwards I ascertained that there was an early carcinoma of the cardiac end of the stomach. This case illustrates the wisdom of compromising with our medical brethren rather than disputing their diagnostic acumen.

There are many cases on record of tumours of the stomach found at operation, believed to be advanced cancer, but in which the patients remained well for many years after exploration. A very distinguished consulting physician in London gave me a verbal description of an operation for suspected cancer of the stomach. An irre-movable mass was found, and the abdomen was closed. As time went on the patient got better, a Wassermann test was made, and was found to be strongly positive. Antisyphilitic treatment completed the cure. Syphilis of the stomach is rare, but not so rare that the differential diagnosis between it and cancer can be ignored. The symptoms are much the same in both conditions, but in syphilis hydrochloric acid is absent much more frequently, and only very rarely can a tumour be palpated.

In September, 1924, I had a lesson in the great difficulty of differential diagnosis. The patient was aged 40, and was a painter by trade. There was loss of weight, loss of appetite, pyrexia, and secondary anæmia, over a period of about six months. Hydrochloric acid was absent and there was some tenderness in the epigastric region, on one occasion he had a slight hæmatemesis. Blood cultures were negative. The radiologists reported that the stomach was dilated, hypotonic, with diffuse narrowing of the pyloric segment, and a gross irregularity of both curvatures. There was a very large six-hour residue. The report added that there was pyloric obstruction, almost certainly due to carcinoma. The clinical and radiographical picture of cancer of the stomach seemed to be complete. Owing to an accident to the x-ray couch at the operation the stomach and first portion of the duodenum were found to be quite normal but in the jejunum, about one foot from the flexure a tumour adherent to the surrounding coils of intestine was discovered. The involved portion was red and inflamed and had the appearance of an acutely inflamed appendix just before perforation. When the loop of intestine was resected the perforations were revealed. The loop of intestine was resected and the condition was found to be actinomycosis, or perhaps a while and the condition was found to be streptothrix infection. The patient died eight days after operation, and at the necropsy a white area of ulceration from the same cause was found in the third portion of the duodenum. In the erect position the stomach lay in front of the ulcerated duodenum which explained the erroneous conclusions derived from the radiologist's report.

Gastric disturbances in pulmonary tuberculosis and in diabetes may simulate carcinoma of the stomach which closely resembled mentions five cases of visceroposis which closely resembled carcinoma of the stomach. I had one case of leather-bottle stomach which stretched and lengthened the gastro-hepatic omentum to such an extent by its own weight that the tumour was felt freely movable in the pelvis, before a radiographical investigation I believed it to be a gynaecological case. This condition, termed "leather-bottle stomach," is renowned for the number of different names indicative of the same condition. It was first described in 1859, and from that date until now there has always been a question as to whether it is histologically malignant or benign. The prognosis in this class of case is always bad.

The Relationship between Gastric Ulcer and Gastric Cancer

This question has given rise to a controversy of great interest. It is well known that Sir Berkeley Moynihan, Mr. Sheeren, and others believe that over 50 per cent of cancer of the stomach arises from chronic gastric ulcers. MacCarty of the Mayo Clinic, who has written frequently on this subject, states that chronic gastric ulcers with a diameter greater than 2½ cm are cancerous, though he is not emphatic as to whether the cancer of the ulcer is primary. There is no doubt about the close association between chronic ulcer and cancer, but there appears to be very great technical difficulties in deciding in what proportion of cases the cancer of the chronic ulcer is the first lesion. Dible, in a recent issue of the *British Journal of Surgery*, states that gastric

carcinoma, so far as can be judged by histological evidence, are in a large majority of cases malignant from the very inception. The last ten stomachs removed in my own practice over a period of eighteen months were investigated histologically from this point of view, but the number is too small and the data too incomplete to serve a useful purpose. I will mention four (three recent) in which there was strong evidence of the development of cancer on gastric ulcer.

1 In 1909 I removed the stomach from a woman in which there was a pyloric stricture, an hour glass stomach at the cardiac end and a malignant growth between the two. It is reasonable to suppose that with the cicatrix following ulcer at either end of the stomach the malignant tumour in the centre was also preceded by ulcer.

2 In 1921 I saw in consultation a clergyman, full blooded and robust, but pain had commenced to follow the ingestion of food, there was vomiting with relief of pain, and marked hyperchlorhydria. At the operation what was believed to be a small chronic ulcer was found in the neighbourhood of the pylorus. It was burnt out by the Balfour method, and a posterior gastro-enterostomy performed. One year later extensive malignant disease of the stomach was established. Pauley and Hampton mention a similar case in which gastrectomy was performed for ulcer cancer secondary to a Balfour operation for ulcer done three years previously.

3 Last year a man, aged 50, was admitted to Mercer's Hospital, and what was believed to be a simple gastric ulcer was found in the pyloric region. With the case of the clergyman in my mind, I performed gastrectomy, and it was only after many sections had been made that a small area with carcinomatous change was found. The change was definitely carcinomatous and not due to distorted or displaced epithelium, often found in connexion with healing ulcers.

4 Two months ago I operated on a patient with an extensive cancer quite inoperable in the pyloric region, and involving the under surface of the liver. Twelve years ago this patient had a perforated gastric ulcer.

On the other hand, most of the cases of carcinoma of the stomach on which I have operated arose as if *de novo*, without symptoms which would suggest the previous presence of chronic ulcer.

As regards palliative operations in advanced cases, in my hands the temporary relief recorded by others has not been experienced. I have tried gastro-enterostomy, jejunostomy, gastrostomy (when applicable), and duodenal feeding, but never with any great success. Anterior gastro-enterostomy is the only operation applicable in some cases, and appears to have a widening field of usefulness. Radium emanation capillaries have not been available at times when I might have used them, but then use as a therapeutic measure in cancer of the stomach, as well as elsewhere, is worth trial. Mayo tried radium through a gastrostomy opening in twelve cases, but none were alive at the end of a year. In cancer of the bladder and cancer of the prostate I have had marked temporary success with this method. In cases of cancer of the stomach I think a two-stage operation is seldom, if ever, necessary. It has been a source of astonishment to myself, the resident staff of the hospital, and the sisters, how little shock or ill effects follow the operation of gastrectomy of the Mayo-Moynihan Polya type, even in cases which appeared to be the very worst surgical risk. Sir Berkeley Moynihan was in the theatre when I performed gastrectomy in this type of case. The following day the patient was reading a book and anxious for food.

I have always performed the sleeve operation when there was sufficient healthy stomach on the cardiac and pyloric side of the growth, and when, as far as I could judge, the growth was precancerous. Once only have I used the Billroth No. 1 operation—sixteen years ago. This patient was alive and well ten years later, but on inquiry from her doctor I learned that during the troubled times she disappeared, and "may have been shot or died from other natural causes." Once I removed a leather-bottle stomach by the Billroth No. 2 method, about fourteen years ago. The patient died some months after the operation.

Gastrectomy, in cases which appear to be on the borderline between the removable and irremovable, appears to me to be well worth while. The immediate results are very satisfactory, and a pleasant surprise may follow in an occasional case.

Two years ago I removed the greater part of the stomach in a man, after mobilization and division of the coronary artery. There was still little or no room for the application of clamps

beyond the growth, yet two years have elapsed and the patient remains in excellent health.

Six months ago I removed the stomach in a very advanced case of cancer. The x-ray report to the local practitioner suggested duodenal trouble and in consequence he believed that procrusteanism was safe. She was a deplorable surgical risk, but gastrectomy was followed with the even convalescence which I have indicated. She has put on weight and is in comparatively good health. A small cancer nodule of the liver was burnt out with the actual cautery.

Once I performed what I believed at the time to be a total gastrectomy, and that for a non-malignant, or perhaps precancerous, condition. The circumstances were as follows.

A woman, aged 60, looked well, the analysis of the stomach contents approached normal, x-ray examinations were negative, but she suffered definitely from gastric symptoms, and I regarded her condition as one which called for exploration. An ulcer was found on the posterior wall about the size of a halfpenny, high up in the cardiac region. The age of the patient and the extent of the ulcer strongly suggested malignancy, but subsequent repeated microscopic examinations proved it to be of the simple type. The gross specimen appears to comprise the entire stomach, and the x-ray photographs taken a month after operation showed the bismuth entering from the oesophagus into the jejunum without any intermediate pouch. Later x-rays showed the development of a cardiac pouch. The operation was performed more than two years ago and it is interesting to note that the patient has never suffered from any of the progressive or intermittent anaemias of the pernicious type which have followed complete gastrectomy in recorded cases. The leaving of even a very minute portion of stomach secures the patient from these serious sequelae. She is at present in excellent health.

I have endeavoured in the above remarks to indicate the direction we should take in the search for early cancer. I have tried to show the weak spots in diagnostic weapons forged to aid us in the battle, and I have striven to provoke discussion on points in connexion with which I seek information from those eminent authorities who are to follow me.

For the thorough and painstaking x-ray investigation of about thirty cases of cancer of the stomach I am indebted to Dr. T. Garratt Hardman, and for the pathological reports on twelve recent specimens removed by gastrectomy I gratefully acknowledge the work of Dr. E. C. Smith of Trinity College. Dr. Maurice Hayes, in several private cases, accurately completed by x-ray examination my clinical efforts at diagnosis.

II—E. I. SPRIGGS, M.D., F.R.C.P.,

Senior Physician, Ruthin Castle (Duff House), Consulting Physician, King Edward VII Welsh National Memorial Sanatorium.

CLINICAL MANIFESTATIONS AND EARLY DIAGNOSIS

The part in this discussion which is allotted to me is to speak of the clinical manifestations and early diagnosis of cancer of the stomach, excluding the use of laboratory methods. I propose to divide my remarks into three parts: first, to give a brief account of the classical symptoms of the disease, secondly, to compare the general picture of the disease with the records of the cases which have been under my own care, referring separately to cancer of the cardiac end, the body, and the pyloric part of the stomach, and, thirdly, to draw certain general conclusions.

Symptoms

The typical picture of cancer of the stomach is that of an elderly man who notices that his appetite has been failing for some months, and who has gradually become conscious of a vague discomfort somewhere above the navel or beneath the breastbone. He brings up more wind than formerly after food, and sometimes a little half-digested food with it, which he will describe as tasting acid, though it will frequently, but by no means always, be neutral or alkaline to litmus. The lack of appetite proceeds to nausea, which may be present before as well as after food, and no eructation may develop into vomiting. This will be irregular, small in quantity, and give little or no relief, or there may be the large infrequent fermented vomit of pyloric obstruction. The discomfort develops into pain, which is then the chief complaint. It is often constant, independent of meals, and may be felt in the pit of the stomach, the small of the back, and between the shoulders. A tumour now is felt situated about or above the navel, or can only be found by putting the hand deep under the seventh and eighth costal cartilages to the left of the epigastrium, or may not be felt at all. Glands may enlarge above the left clavicle and in the left axilla. By this time the look of health is

gone, there is an anxious expression, a loss of weight, of colour, and of vigour. As soon as the surface of the growth in the stomach has begun to ulcerate, mucous debris, and digested blood, giving the coffee-ground appearance, are seen in the vomit. A large hæmorrhage may occur, but this is regarded as more characteristic of simple ulcer than of growth.

An irregular mild fever may now develop, and surrounding structures may be involved in the progress of the growth, until at length nutrition fails, and, within two years of the first symptoms, the vital powers are overtaken.

COMPARISON OF THE SYMPTOMS IN A CONSECUTIVE SERIES OF CASES

I pass now to a comparison of the above picture with the records of 25 consecutive cases at Duff House and Ruthin Castle, in which the diagnosis was made or confirmed by a clinical examination, combined with the radiological, chemical, or operative findings. The series is small, but it excludes all patients in whom for any reason the history or the observations were inadequate. There were 21 men and 4 women, and the average age was 61 years—the youngest was 39, 14 were 65 or over. In this comparison I shall refer to early symptoms only, for the developed picture is a hopeless one.

These cases support the general experience that the history of the disease is commonly of short duration, for in 17 of them the onset of symptoms was recent, ranging from three months to two years before admission, with an average of eleven months. Four patients, however, had had lifelong indigestion, in one of these an ulcer crater was demonstrated, and two of them had tubular leather-bottle stomachs. Christopher Graham states that in over 40 per cent of cases there is a long history of ulcer. In this small series the proportion was not so great. In 7 other patients, however—that is, 28 per cent—including some who gave short recent histories, inquiry elicited that they had had indigestion in youth, with a long period, up to thirty years or more, of freedom, until the present illness began. This type was also referred to some years ago by Graham. He gives the proportion of patients displaying recent symptoms only as 58 per cent, in our series it was very close to this—namely, 56 per cent. It is clear, therefore, that whilst absence of indigestion before the illness is significant, occurring, as it did, in the account as given by four-fifths of the patients, no reliance must be put on a previous history of indigestion as excluding the probability of cancer in an elderly person.

As regards the few cases with a history of ulcer preceding definite cancerous symptoms, to which may be added those in which careful inquiries showed that there had been definite indigestion in youth for two or three years, which had passed off, no one can deny that these affections of the stomach probably had a share in predisposing to the development of cancer, and from this I draw the conclusion that if every case of persistent dyspepsia were investigated by modern methods, and suitable treatment, medical or surgical, applied, not only would much ill health be avoided, but it is more than probable that the number of people affected with cancer of the stomach would be less.

In 4 patients the growth was in the cardiac end, in 10 in the lesser curvature and body, of whom 3 showed a tubular leather-bottle stomach, and in 10 the growth was in the pyloric part.

In carcinoma of the cardiac end discomfort or pain may be felt to the right of the epigastrium, behind the sternum or in the back. Anæmia may be slight or absent up to a short time before death. Belching and regurgitation are prominent the picture passing later into one of oesophageal obstruction. A cancer is most likely to be undetected in this situation because of the position of the tumour, and especially if associated with some other illness of later life such as chronic bronchitis or disease of the kidneys.

In growths of the body of the stomach, the early symptoms were in unpleasant sensation in the chest, verging into pain and loss of appetite, or in some sense of hunger. Pain at a definite interval after food was a feature in several.

In all the cases of a tubular or leather bottle stomach, nausea and aversion to food were the prominent symptoms.

Such aversion may be combined with a hunger pain, which is relieved by food. There is usually no delay in these stomachs. The food rushes through the rigid lumen to a gaping pylorus.

In the cases of carcinoma of the pyloric part of the stomach an account is frequently given of pain one to three hours after food which might be relieved by food but often was not. In several a diagnosis of duodenal ulcer had been made. The cases differ from typical ones of duodenal ulcer in that the account of the daily round of symptoms varies, is less definite and clear-cut, also in that flatulence, nausea, and eructation are more frequent in cancer, with loss of appetite, weakness, and depression. There may be, however, with a well developed growth, no loss of weight and no anæmia, and it is precisely these cases which respond best to early excision. Such a growth, for example, in this series, was resected eighteen months ago by a distinguished surgeon who is taking part in this discussion, and the patient is now doing full work.

Dilatation of the stomach with vomiting of large quantities every two or three days may be the first sign of a growth at the pylorus. I have, of course seen this, many of us have, but it is uncommon, and when pyloric obstruction is almost complete with great dilatation of the stomach, both clinically and radiologically, there may be no vomiting, as in 3 out of 5 cases of pyloric obstruction in this series. Indeed, excluding acute and subacute gastritis, the cause of vomiting as a general symptom more often lies outside than inside the stomach. I must refer again to the importance of remembering that more than one lesion may be present and confuse the picture, as in a case in which a gall stone was present.

In three cases a large hæmatemesis was the first symptom, in one of these the growth was at the cardiac end and arose around an ulcer, in one it was on the greater curvature, and in one in the pyloric part. Of the anxious foreboding expression, which is described as a feature of cancer of the stomach, I will say this: it is, when present, characteristic and permanent, but the anxiety is not so intense, and particularly not so freely expressed, as that of a nervous patient with an innocent dyspepsia which he fears may be malignant.

There are cases—there were two in this series—in which the disease is beyond help before there are any reasonable clinical grounds to suspect, still less to diagnose, carcinoma of the stomach, though on looking back when all the facts are known an indication can sometimes be recognized. Such cases, are, however, in my experience, generally obscured by an accompanying affection, for, though the early stages may be symptomless I have not known a growth of the stomach to be found in a man who could be called healthy. Here is an example of such an insidious growth.

A man, aged 66, developed pneumonia a crisis came on the tenth day. Recovery was slow the consolidation not clearing up. On one day only during convalescence he had abdominal pain for a few hours. He became apparently well and remained so in active work, for six months when health began to fail. There was no digestive symptom except that for some years at least, he had brought up wind after a meal. On investigation the chest showed the picture on the screen. Consolidation of the upper lobe of the right lung was present but was thought to be a secondary growth which had given rise to pneumonia eight months before. There was adhesion of the right wing of the diaphragm. An advanced growth of the body of the stomach was found with typical rapid emptying and a gaping pylorus. The growth of the lung was probably secondary to the unsuspected growth of the stomach.

Sir William Wheeler has described the main points in the differential diagnosis. The difficulties are greatly lessened if a careful examination of the patient is made by modern methods. The gastric symptoms of cancer of the stomach are simulated by gastric and duodenal ulcer, gall stones and chronic appendicitis which are all frequent, and by benign growths and syphilis of the stomach, which are rare. The constitutional symptoms—namely, weakness and anæmia—are common features of pernicious anæmia, Bright's disease, tuberculosis and malignant growth elsewhere in the body, but they may also be caused by a host of other diseases which however a complete examination of the patient, including the laboratory tests, will as a rule eliminate.

CONCLUSIONS

The clinical study of every case of disease is of the first importance in the practice of medicine. It can never be eliminated or replaced by laboratory methods or exploratory operations. It is the first step on the ladder of our endeavour to help the patient, but it is only the first step. Cancer of the stomach has been known from time immemorial, and I suppose no disease has received more clinical study with less result as regards early recognition and treatment. Of this the protean nature of the symptoms and the frequent variations from type which I have been describing are explanation enough. Essential, therefore, as is a study of the symptoms, and especially of the early symptoms, is it my conclusion that by taking thought an adequate diagnosis can be made? It is not. It is the opposite. The attitude of a doctor often is that he should come to a suspicion of cancer reluctantly—that is to say, slowly. This is wrong and loses many lives. There should be no slowness. The case should not be "watched." When a diagnosis is made by such methods the prognosis is hopeless.

In every doubtful and unexplained case of indigestion, loss of appetite, or failing strength, early and rapid steps should be taken to exclude cancer of the stomach, without waiting for anaemia or cachexia. Of these the most important is an x-ray examination. By this I do not mean the taking of one or two antero-posterior photographs of the barium-filled stomach at fixed hours, I mean a careful watching on the screen of each part at different angles throughout the passage of the meal from the gullet to the duodenum, taking frequent photographs with short exposures. If after such an examination the stomach is passed by a good observer, it is most unlikely that it is the seat of growth. In all cases in which the examination is not completely negative, or in which any deformity seen is not fully accounted for, an exploration should be made at once in order that the patient may have the only chance which our present knowledge offers of the complete removal of the disease.

Physician to Guy's Hospital

AUXILIARY METHODS OF DIAGNOSIS—RADIOLOGICAL AND CHEMICAL

Four years of work with a diagnostic team has dispelled a good deal of my former pessimism with regard to the possibility of diagnosing cancer of the stomach at a stage in which radical treatment is still possible. We must depend, in the first instance, upon the recognition by the general public that instead of trusting themselves with patent medicines they should at once seek medical advice for digestive symptoms of a kind they have not previously experienced. Secondly, the general practitioner must recognize that if the symptoms described by Dr. Spriggs are not the result of some obvious cause and do not rapidly respond to simple treatment, the patient should undergo a complete investigation with the object of settling the diagnosis. I believe that it is possible in a very large majority of cases to decide definitely within ten days of taking a patient into a hospital or clinic whether the likelihood of cancer of the stomach is sufficiently great to warrant operation. The diagnosis can often be established with certainty, in the remaining cases it can be made with so great a measure of probability that an exploratory operation becomes the only justifiable treatment, even if the symptoms are of short duration or slight in degree. It is true that occasionally at operation no organic disease is found or the disease is of a less serious nature than was anticipated, but this is more than counterbalanced by the fact that it is very rare indeed for the diagnosis to be missed after a complete investigation. If the patient consults his doctor at the right time, and his doctor appreciates the value of a complete investigation in suspicious cases, a diagnostic team should be able to obtain sufficient evidence to decide whether an operation is indicated or not within a month of the onset of symptoms.

If a thorough investigation is only carried out in cases

in which cancer of the stomach appears to be the most likely diagnosis, many early cases will escape recognition. Such an investigation should be carried out in all suspected cases of organic abdominal disease before beginning treatment, whether medical or surgical, even if the diagnosis appears to be obvious, and also in cases of impaired general health, loss of weight, loss of strength, anorexia and anaemia, in which a sufficient explanation is not

found. In every case there are three methods, namely, x-rays, radiography, and barium meal helps in many cases, but reliable results can only be obtained when the tests are carried out by observers who are familiar with the fallacies of the methods and how they can be avoided.

The statistics I shall refer to have been prepared for me by Dr. N. L. Lloyd from the records of fifty cases investigated at Guy's Hospital and by Dr. J. F. Venables from a consecutive series of seventeen private cases investigated at New Lodge Clinic. Their results will be published in the October number of the *Guy's Hospital Reports*.

1. TEST MEAL

A fractional test meal properly carried out and properly interpreted gives very valuable information in a considerable proportion of cases of cancer of the stomach. The questions to consider are (a) the character of the "resting juice," (b) the acidity during the meal, and (c) the presence of blood.

(a) The Resting Juice

It is essential that the stomach should be completely evacuated before the meal is given. The "resting juice" obtained does not often exceed 50 c.c.m. in normal individuals, though it may be as much as 100 c.c.m. More than 50 c.c.m., and certainly more than 100 c.c.m., suggests the presence of some difficulty in gastric evacuation. The presence of visible food residue or of dissolved starch or sugar in the juice points strongly to organic pyloric obstruction; this can be diagnosed with certainty if the quantity of food is considerable and if much of the test meal is still present when the stomach is finally emptied at the end of three and a half hours. If in these cases free hydrochloric acid is present, an ulcer is the probable cause; if no free acid is present, and especially if the material removed is of uniformly thick consistence, a growth is almost certainly present. The diagnosis is rendered still more probable if it has a foul odour and contains excess of organic acids.

In the absence of pyloric obstruction information as to the existence of a growth can only occasionally be obtained by examining the resting juice. Bennett has laid stress on its foul odour in cancer of the stomach, but this was observed in only two of our cases, and Dr. T. W. Turner tells me that it was present to an equal or greater extent in several of our cases of achlorhydria due to other causes.

Some French observers pay great attention to the microscopic examination of the resting juice. But Graef, working in my clinic, found that the epithelial cells and pus cells in the resting juice were almost invariably present in the same proportion as in the spittle examined at the same time, and the large number seen in cases of achlorhydria was due to the pus and epithelial cells swallowed with the saliva remaining undigested in the stomach. Microscopic examination of the resting contents is therefore only of value if the spittle is examined at the same time; in some cases of cancer great excess of pus cells is found in the resting juice in comparison with the spittle, so far as our experience goes this does not occur in chronic gastritis with achlorhydria or in any other condition.

(b) Acidity

The value of the fractional test meal as compared with the old-fashioned one hour test is shown by the fact that in a consecutive series of 1,000 fractional test meals at New Lodge Clinic complete achlorhydria was found in 15.2 per cent, but free hydrochloric acid was absent in the one hour fraction in 7.4 per cent. In additional cases, these would have been regarded as having achlorhydria if the contents of the stomach at the end of an hour had alone been analysed.

The importance of this is well seen in cancer of the stomach, in which the old method showed achlorhydria in 80 per cent of cases, but with the fractional test meal free acid was absent throughout in only 63 per cent of our cases and 50 per cent of a Mayo Clinic series reported by Hartman.

The presence of free hydrochloric acid cannot therefore be regarded as evidence against the diagnosis of a growth. On the other hand, though complete achlorhydria is present in 4 per cent of normal young men (Bennett and Ryle) and in 15.2 per cent of 1,000 medical cases admitted to New Lodge Clinic, in which it seemed desirable to give a test meal, its presence must still be regarded as a point in favour of a growth if the other evidence points in the same direction. It is of special help in the diagnosis from gastric ulcer, as achlorhydria was only present in one out of a consecutive series of fifty cases at New Lodge Clinic. The presence of achlorhydria is, however, of no help in diagnosing from Addison's anaemia, in which it occurs in 100 per cent of cases, or from syphilis of the stomach, in which it is also generally present. Achlorhydria is common in severe chronic gastritis, which is generally secondary to alcoholism or oral sepsis, but whereas in our experience lavage of the stomach before the test meal is given only rarely leads to the subsequent appearance of free acid in cases of growth, it does so in most cases of chronic gastritis, as well as in all of chronic gastric ulcer, as in these conditions the achlorhydria is due to the neutralization of the free acid with the excess of all other mucus which is always present. Whenever, therefore, we discover achlorhydria, we invariably repeat the test meal a few days later after preliminary lavage, if it is still present in a suspected case of chronic ulcer, the ulcer should be regarded as probably malignant, and doubt should also be thrown upon a provisional diagnosis of chronic gastritis. In one case in which the symptoms and x-ray appearance suggested a simple ulcer becoming malignant, in which achlorhydria was replaced by hypochlorhydria after lavage, I advised partial gastrectomy, the marked x-ray appearance was suggestive of a large chronic ulcer becoming malignant, but microscopic examination showed that it was tuberculous.

In the achlorhydria of cancer of the stomach some hydrochloric acid is probably secreted, as the organically combined chloride is often, and the mucogenic combined chloride is generally greater than normal. This distinguishes it from the large majority of cases of achlorhydria, caused by constitutional achylia gastrica, an inborn error of gastric secretion which is present in about 4 per cent of normal people and is a predisposing factor of varying importance in a number of diseases, such as Addison's anaemia and subacute combined degeneration (100 per cent), gall stones (49 per cent), and chronic appendicitis (33 per cent).

(c) The Presence of Blood

In 44 per cent of our cases obvious blood was present in every fraction in sufficient quantity to tinge the whole specimen; in an additional 18 per cent it was present in one or more fractions. It is rarely present in sufficient quantity to be recognized with the naked eye in gastric or duodenal ulcer unless there has been a recent hæmorrhage, and it is still more rarely seen in other conditions. Its constant presence in association with achlorhydria has only been observed by us in cancer of the stomach. The only case I have seen of Addison's anaemia with blood in each fraction of the test meal proved to be secondary to the achlorhydria caused by a growth of the stomach.

2 RADIOGRAPHY

In the New Lodge Clinic series the x-rays showed definite evidence of the presence of a growth in every case. In the Guy's Hospital series the results were much less satisfactory, definite evidence being obtained in only 50 per cent of cases. The discrepancy is due to the fact that in the former the examinations were all carried out by Dr P. J. Briggs, who is an expert in the radiology of the alimentary tract, whereas at Guy's Hospital, owing to the pressure of work, the examinations were carried out by various observers, some of whom had had comparatively little experience. With good technique and an experienced observer I think that some abnormality suggestive of growth would be discovered with the x-rays in almost every case. The

radiological evidence is, however, not yet quite so trustworthy as in the case of gastric and duodenal ulcer. I am nowadays unwilling to diagnose an ulcer without direct radiological evidence of its presence, but if the other evidence was very strong I would be prepared to advise operation in a case of suspected carcinoma of the stomach, even if nothing abnormal had been seen with the x-rays.

Though a definite deformity can generally be recognized in the outline of the stomach in good radiograms, it is remarkable how normal the appearance may be, even with growths of considerable size. For this reason the screen examination is of still greater importance, especially with early growths involving the pyloric half of the stomach. In most of these cases careful observation reveals some abnormality in the peristaltic waves. Instead of becoming slowly and steadily deeper as they approach the pylorus, they may disappear entirely, or they disappear and reappear an inch or more further along the curvature. We have often observed this in the absence of any permanent filling defect which could be recorded on a radiogram. Unfortunately it is in the cardiac half of the stomach, in which peristalsis does not normally occur, that filling defects are most likely to be missed, though this should rarely occur if the patient is examined in various positions, especially in the Trendelenburg position, which results in the fundus being completely filled with the opaque meal.

Until recently radiologists experienced great difficulty in deciding whether pyloric obstruction was due to cancer or some other cause. We have found that the difficulty can be overcome by completely emptying the stomach with a Senoian's evacuator before the opaque meal is given. In pyloric obstruction the stomach always contains fluid and often some food residue when the patient is fasting in the morning. Consequently, when the opaque meal is swallowed it drops to the bottom of a distended stomach. The transparent gastric contents are generally not observed, a diagnosis of dilatation due to obstruction is made, but as the opaque meal lies in the most dependent part of the stomach the immediate neighbourhood of the obstruction is not clearly seen. After being evacuated it is found that, though previously distended, the stomach is not permanently dilated, as it never always contracts to a normal or almost normal size. Consequently an opaque meal taken now fills the stomach in a normal manner, and the outline of the pyloric end of the stomach and the progress of the peristaltic waves from their commencement to their end can be satisfactorily investigated.

I have seen a number of cases in which the most careful abdominal palpation failed to reveal any tumour, but on repeating the examination under the x-ray screen, when the stomach was visualized, it has been possible to recognize a thickening when an irregularity in outline or an abnormality in peristalsis was observed, the method of combined radiography and palpation, which should be carried out by the clinician and not the radiologist, because of the necessary exposure of the hands to the x-rays, may therefore be of great value when neither method alone has led to a conclusive result.

3 EXAMINATION OF THE STOOLS FOR OCCULT BLOOD

So far from agreeing with Sir William Wheeler that the test for occult blood in the faeces "contains too many fallacies to be of any practical importance," I regard it as a test of the very greatest value. When blood is swallowed or is derived from an ulcer or growth in the alimentary tract, it is evacuated in the stools partly as acid hæmatin and partly as hæmatoporphyrin. The chemical tests for "occult blood"—traces of blood insufficient to produce any change in the appearance of the faeces—depend upon the conversion of a substance with little or no colour, such as guaiac or benzidine, into a coloured substance when oxidized by hydrogen peroxide in the presence of a carrier, such as hæmatin. Hæmatoporphyrin, which contains no iron, does not give the reaction. The stools should also be examined with the spectroscope, as traces of hæmatoporphyrin, which is occasionally present in the absence of acid hæmatin, would otherwise escape recognition. Moreover, a positive spectroscopic finding is a valuable confirmation of a positive chemical reaction, as, although it is much less sensitive, there is less chance of error.

Before examining the stools the patient is given a haemoglobin free diet. Chlorophyll should also be excluded, as it gives a feebly positive guaiac reaction and its many banded spectrum may cause confusion in the spectroscopic examination. A charcoal biscuit is given with the first meal on the restricted diet, and the first and subsequent stools passed when the faeces are no longer blackened by the charcoal are examined. For the guaiac and spectroscopic tests a small amount of faeces is macerated with glycerol rectic acid into a thin paste. An equal quantity of ether is then added to extract the pigment, the ethereal extract is poured off, some being kept for the spectroscopic examination. Two or three drops of tincture of guaiac are added to the remainder, a small quantity of ozone alcohol is then poured in, and a changed colour is looked for at the junction of the two fluids. A "positive reaction" is one in which a deep blue colour rapidly appears, a "feebly positive" reaction is one in which the colour is faint purple, bluish, or greenish. A positive guaiac reaction signifies the presence of occult blood, and a positive spectroscopic examination shows that it is present in fairly considerable quantities. A negative guaiac reaction proves the absence of occult blood, except occasionally at the end of a period of haemorrhage, when the spectroscopic test may alone be positive, as the traces of blood still present may then be completely converted into haematoporphyrin, which gives a characteristic spectrum, but does not give the chemical reaction.

With the technique described no sign is of more value than the discovery of occult blood in the stools. I have never seen a growth, either of the stomach or the colon, in which occult blood was not present. Thus the guaiac test was positive in 100 per cent of the Guy's Hospital and New Lodge Clinic cases, and a haematoporphyrin spectrum was given in 91 per cent of cases. It is true that occult blood is also present in nearly all cases of active ulcer of the stomach and duodenum, but the very appearance of these two conditions is so characteristic that difficulty in diagnosis rarely occurs.

I am a great believer in the medical treatment of gastric and duodenal ulcer so long as no hour-glass contraction or pyloric obstruction is present. The danger of failing to recognize that a chronic ulcer is becoming malignant is not great, as the x rays generally settle the question at once. But in the very earliest stages the appearance may still be that of a chronic ulcer. In such cases the immediate result of treatment does not help, as the symptoms disappear as quickly as in an uncomplicated ulcer. The crater of the ulcer also becomes smaller, though it does not disappear completely, as it does in nearly all cases of chronic gastric ulcer. But what is of far more importance is that occult blood persists, however long the treatment continues and however well the patient appears to get. If, therefore, at the end of a fortnight's treatment symptoms are still present, or at the end of a month the crater has not either disappeared or become much smaller, or, most important, if occult blood is present in undiminished quantity, an operation should be advised without further delay. In a considerable experience I have only once failed to recognize that an ulcer was becoming malignant, and generally within a fortnight of the commencement of treatment. The one exception is of such importance as demonstrating the value of looking for occult blood compared with all other methods of examination in cases of this kind that I must briefly relate the history of the case.

Gastric Ulcer becoming Malignant whilst under Observation

A man aged 66 had had typical symptoms of gastric ulcer for four years. On admission to New Lodge Clinic on February 23rd 1924 the diagnosis was confirmed by the discovery with the x rays of a large crater on the lesser curvature, this was coated with hyperchlorhydria and the constant presence of occult blood in the stools. Though all symptoms disappeared within a week, I wrote to the patient's doctor when he went home in order to continue treatment after being three weeks in the clinic, that if occult blood is still present after a few more weeks the question of operation should be reconsidered, as this is just the type of ulcer which undergoes malignant degeneration. The patient returned for re-examination on April 11th and again on May 18th, the x rays showed that the crater was much smaller but as occult blood was still present I advised a continuation of strict treatment. He returned for the third time on June 22nd. He felt and looked strong and well, had gained 5 lb in weight since his first admission and had had no trace of indigestion. At this stage I thought that the small deformity still seen with the x rays must represent a scarred depression in the pancreas

produced in the healing of the ulcer. I was very satisfied that I did not feel simply because a trace of occult blood was present in the stools.

Early in August for the first time since the commencement of treatment he experienced pain it was quite different in character from the old ulcer pain and was accompanied by nausea and anorexia. No relief followed careful dieting and he returned to the clinic on August 31st. He had gained another 4 lb in weight since June. Nothing abnormal was felt on abdominal examination. Occult blood was still present in the stools and a most remarkable change had taken place in the x ray appearance in the nine weeks which had elapsed since the last examination. Instead of a very small niche with a smooth outline there was a large irregular deformity which was unmistakably due to malignant disease. The hyperchlorhydria was still present in undiminished degree.

A few days later Mr L. Bromley performed a partial gastrectomy. A large thick scar was found on the lesser curvature its centre formed a smooth walled depression in the pancreas. Microscopic examination showed that carcinomatous change were occurring on one side of the scar and that the neighbouring mucous membrane was becoming infiltrated. There were no enlarged glands or secondary deposits. In spite of radiotherapy signs of a secondary deposit in the spine appeared seven months later.

There can be little doubt that the persistent occult blood was due to the fact that malignant degeneration had already begun in March. This sign, therefore, preceded the earliest symptoms by five months and the earliest radiological changes by at least three months, and no diminution in gastric secretion had occurred in six months. The case also shows how little reliance can be placed on a gun of weight, contrary to what Sir William Wheeler suggested, I believe that the majority of patients with cancer of the stomach gain weight after a fortnight in bed with careful dieting.

EXAMINATION OF THE BLOOD

In every suspected case of cancer of the stomach the blood should be examined. But it is of the greatest importance to recognize that anaemia is not always present, though it may be severe, in one of our cases the haemoglobin percentage was only 23. Thus in two advanced cases, in one of which the whole organ was infiltrated to form a leather bottle stomach, the haemoglobin percentage was 95, and in another case the percentage was actually 103.

I hope that Sir William Wheeler's suggestion that the group of cases in which anaemia is the most prominent symptom should be described as the "pernicious anaemia type" of cancer of the stomach will not be adopted. There should never be the slightest doubt about the diagnosis of Addison's (so called "pernicious") anaemia from cancer of the stomach. The difficulty in the past has arisen from the character of the blood picture, which the majority of haematologists required before making a diagnosis of Addison's anaemia. We now know, largely as a result of Price-Jones's work, that the only constant feature of the blood in Addison's anaemia is megalocytosis. This occurs in no other condition likely to be mistaken for growth, it is present in the very earliest stages of the disease, as, for instance, in most cases of subacute combined degeneration of the cord or Hunterian glossitis, in which no actual anaemia has yet developed, and it also persists after apparent recovery, when the haemoglobin percentage may be over 100, although in such conditions none of the other features, such as the presence of megaloblasts or poikilocytosis, are present. Moreover, in Addison's anaemia, though achlorhydria is always present, the stomach is normal in size and outline, and occult blood is never found in the stools, in the active stages, in which difficulty in diagnosis might possibly arise, the indirect van den Bergh test is positive, though the direct is negative, whereas in cancer both are negative, unless jaundice is present as a result of secondary deposits in the liver, in which case both are positive.

Megalocytosis is never present in uncomplicated cancer of the stomach. I have however, seen two cases, and others have been described, in which Addison's anaemia occurred as a complication when the cancer had led to complete achlorhydria, so that the essential predisposing conditions for the development of the disease were present. But as the anaemia is secondary to the growth it only appears at a late stage, in which there is no longer any possibility of radical treatment.

In this connexion I should like to refer for a moment to a remark made by the opener with regard to gastrectomy. I feel sure he is wrong in believing that the possibility of Addison's anaemia developing as a sequel to the operation can be prevented by leaving a very minute portion of the stomach. Gastrectomy causes complete achylia, consequently oral sepsis may lead to secondary infection of the intestine, and in 1910 instances to the development of haemolytic and neuro-toxic poisons, which give rise to Addison's anaemia and subacute combined degeneration of the cord. The danger is present to a less extent after partial gastrectomy, and even after gastro-enterostomy, if complete neutralization of the acid which is still secreted occurs, though of course only with total gastrectomy is absolute achylia produced. The danger can be easily prevented if before every gastric operation, whether total or partial gastrectomy or simply gastro-enterostomy, all oral and naso-pharyngeal sepsis is as far as possible eradicated.

The Wassermann reaction should always be ascertained in a hundred consecutive patients at New Lodge Clinic, none of whom showed any obvious signs of syphilis or of a disease known to be due to syphilis, a positive reaction was obtained only once. It is clear, therefore, that a positive reaction in a case of suspected cancer, at any rate in better-class practice, should be regarded as of considerable significance. One group of cases of syphilis of the stomach is clinically almost indistinguishable from cancer, as the x rays show a deformity, acholhydria is present and occult blood may be present in the stools. If in such a case a positive Wassermann reaction is obtained and the patient appears to be in better general health and has lost less weight than one would expect from the extent of the disease, a trial of active antisyphilitic treatment should be made, especially if it seems unlikely that the whole mass in the stomach could be completely removed. But if obvious improvement does not occur within two or three weeks there should be no further delay. I have myself seen three cases of proved cancer of the stomach in patients whose blood gave a positive Wassermann reaction.

IV—MATTHEW J. STEWART, M.B., F.R.C.P., Professor of Pathology University of Leeds

PATHOLOGICAL GENERAL RELATION OF CANCER TO ULCER

My contribution to this discussion will consist of two parts—(A) a brief review from the morbid anatomical standpoint of 165 cases of cancer of the stomach seen during the last fifteen years in the post-mortem room at Leeds, and (B) a short account of my personal experience of the relation of ulcer and cancer, based on the detailed microscopic examination of 216 stomachs or portions of stomachs removed at operation.

A SOME PATHOLOGICAL ASPECTS OF CANCER OF THE STOMACH

Age and Sex Incidence

The age and sex incidence in 165 cases seen in the course of 7,930 consecutive post-mortem examinations was as follows:

TABLE I.—Age Incidence

0-9	0.0 per cent	40-49	28.5 per cent
10-19	0.6	50-59	32.7
20-29	0.6	60-69	20.7
30-39	13.3	70-79	3.6

Thus 82 per cent of the cases in this series occurred between the ages of 40 and 70. The youngest patient was aged 18, the eldest 76.

The sex incidence was 113 males to 52 females—a male preponderance of rather more than 2 to 1.

Topographical Distribution

In trying to determine as accurately as possible the primary point of origin of chronic ulcer and of cancer I have analysed a series of 248 cases from the post-mortem room, 13 cases of cancer in which the whole or almost the whole organ was involved have been excluded, leaving 235 cases in which

accurate information as to site was available—namely, 115 cases of chronic ulcer alone, 110 of cancer alone, and 10 in which it was considered that the cancer had probably originated in a simple chronic ulcer. For topographical purposes the stomach was divided into four areas: (1) the pylorus and prepyloric inch, (2) the cardiac end, including both the cul-de-sac and the immediate neighbourhood of the oesophageal orifice, (3) the lesser curvature and immediately adjacent portions of the anterior and posterior walls, but stopping short about one inch from either ostium, and (4) the rest of the organ. In each case the centre of the lesion has been regarded as the starting point except that all cancers abutting on the pyloric ring have been included in the pyloric and prepyloric group.

TABLE II.—Position of Chronic Ulcer and Cancer of Stomach

	Chronic ulcer (125 cases)	Cancer (110 cases)
Pylorus and prepyloric inch	17.5 per cent	67.0 per cent
Cardiac end	0.0	16.5
Lesser curvature region	73.0	11.5
Rest of stomach	9.5	5.0

The observation of clinical specimens confirms these results, at least in respect of the salient facts that the great majority of simple chronic ulcers occur on the lesser curvature well away from the pylorus while cancer, when it occurs in the distal two thirds of the stomach, is most frequent at or close up to the pyloric ring. This, it seems to me, is an important piece of evidence against the very intimate relationship between ulcer and cancer claimed by some authors. Another interesting fact emerging from the present series is that of the 10 cases in which cancer had apparently arisen in a pre-existing simple ulcer, 9 were in the lesser curvature region as above defined and only one near the pylorus. The same fact may perhaps be stated more interestingly by saying that of 14 cases of cancer arising in the lesser curvature region no fewer than 9 had originated in a simple chronic ulcer.

Glandular Dissemination

In 21 of the present series of 165 cases of cancer partial gastrectomy had been performed, and this group is excluded in considering local lymph gland metastasis. Of the remaining 144 cases, 104, or 72.2 per cent, showed obvious nil else involvement of adjacent lymph glands, those in the lesser curvature of the stomach most frequently, but very often those along the greater curvature and in relation to the head and body of the pancreas as well. Involvement of the subpyloric glands and of those in the portal fissure was frequent. It is fairly certain that the figure quoted above is an underestimate, as all the autopsies were not done with equal care.

In considering more remote metastasis, the whole series of 165 cases is included. (a) In 26 cases (16 per cent) there was more or less extensive involvement of the lumbar (periaortic) glands, always with well marked local gland involvement. (b) In 17 cases (10.3 per cent) there was intra-thoracic lymph gland involvement, and in only 5 of these was this unaccompanied by downward extension along the abdominal aorta. (c) In 9 cases (5.5 per cent) there was involvement of the supraclavicular glands—in 7 (4.2 per cent) on the left side only, in 2 on both sides. Intra-thoracic metastasis coexisted in 7 of these cases, including the 2 in which the supraclavicular adenopathy was bilateral. The 2 remaining cases, both left-sided, are probably examples of direct thoracic duct metastasis. In one the local gastric glands only were involved, in the other partial gastrectomy had been performed ten months before, and, apart from local recurrence in the gastrojejunum and stomas, the left supraclavicular adenopathy was the only cancerous lesion found.

Peritoneal Dissemination

This was present in 42 cases (25.5 per cent), and in 25 of these it was both extensive and profuse. Ascites in large amount was present in 11 cases, being associated with peritoneal metastasis in 7, with extensive hepatic involvement in 2, and with both these lesions in 2. Pleural dissemination occurred in 3, pericardial in 2 cases.

Visceral Dissemination

1 Direct extension to adjacent organs occurred with the following frequency: pancreas 9 times (54 per cent), transverse colon 8 times (48 per cent) (once with formation of a gastro-colic fistula), spleen 6 times (36 per cent), liver 5 times (30 per cent), and kidney once (0.6 per cent). In 8 cases (48 per cent) the tumour had transgressed the pylorus and invaded the duodenum.

2 The frequency of metastatic deposits is shown in the following table:

TABLE III—*Visceral Metastasis in Cancer of Stomach*

	No of Cases	Incidence Rate
Liver	44	26.6 per cent
Ovaries	10	19.2* "
Adrenals	6	3.6 "
Kidneys	3	1.8 "
Pancreas	3	1.8 "
Spleen	2	1.2 "
Heart	1	0.6 "

* Female cases only

In 3 cases there was a metastatic deposit at the umbilicus. Of the 10 cases of ovarian metastasis, 6 were bilateral, and in 7 there was an accompanying peritoneal dissemination, local or general. Of the 3 cases in which ovarian metastasis was unaccompanied by other evidence of peritoneal dissemination, 2 were right-sided and 1 bilateral.

The largest livers in the series weighed 176, 188, and 196 g respectively. Definite jaundice was present in 5 cases. In one of the cases with liver metastasis, there was extraordinary infiltration of the walls of all the main bile passages.

It is interesting to note that in 20 cases which died as a result of the operation of gastrectomy, there were 3 in which the whole of the disease had not been eradicated. In one a portion of cancerous stomach still remained, in the second there was a single metastatic nodule in the liver, while in the third there was extensive invasion of the lumbar lymph glands. In 2 cases the carcinoma had originated in stomachs which were already the seat of generalized polyposis, and in a third there was a single large polyp springing from the pylorus.

Perforation and Haemorrhage

In 16 cases of the present series (9.6 per cent) perforation, acute or subacute, had occurred, with resulting general peritonitis in 12 cases, and in the remainder perigastric abscess, peritonitis of the lesser sac, subphrenic abscess, and gastro-colic fistula respectively. It is worthy of note that 5 of the 16 were regarded as instances of ulcer-cancer, and in these it was the ulcer rather than the cancer which had perforated. In my series of 150 cases of fatal chronic ulcer previously reported¹ the incidence of perforation was 38.5 per cent.

Severe haemorrhage in the cancer cases was even less frequent, although, of course, intermittent haemorrhage in small amount is practically constant. In two cases only was haemorrhage regarded as the proximate cause of death, and in only one other had bleeding been at all profuse. In all three there had been a recent gastro-enterostomy. In the chronic ulcer series haemorrhage was the immediate cause of death in 8 per cent.

B THE RELATION OF ULCER AND CANCER

I or obvious reasons conclusions on this point are drawn from operation specimens only, and of these I have examined to date 216 examples. With the exception of two or three cases in which local excision was practised, the operation was that of partial gastrectomy, and the specimens have been delivered to me in the fresh, untouched state. The method of examination has been, after inspection of the exterior, to lay open the portion of stomach, usually along the line of the greater curvature, and to pin it out flat on a lint-covered board. This has then been floated, specimen downwards, in a large tank of formalin (Kuserling's No 1 solution) for a few days, after which the specimen has been sliced up for histology. The method has the disadvantage of giving an artificial

and to some extent untrue view of the relation of the various parts of the lesion, but it has the incomparable merit of permitting the closest possible naked-eye scrutiny of the inner aspect of the ulcer or growth while the specimen is still in the fresh state. It then becomes possible to make one's cuts in such a way that the most suspicious parts can be taken for microscopic examination, while a portion may still be available for mounting as a museum specimen if desired. It has been an invariable practice for some years now to make a rough sketch of the specimen so pinned out while it is still fresh and unaltered, noting the exact shape and position of any ulcer, growth, or scar which may be present, and any other points of interest, especially with a view to subsequent histological study.

It may be stated at the outset that in only one case of simple chronic ulcer was unsuspected malignancy found microscopically, while one case of apparently uncomplicated cancer (but with a two years' history) was found to show microscopic evidence of pre-existing simple ulceration. In a third case what was supposed by naked eye examination to be a simple ulcer became malignant failed, on microscopic examination, to show any evidence of pre-existing simple ulceration.

The histological criteria for the differentiation of ulcer-cancer from the uncombined lesions have been clearly stated by Dible in his recent paper,² and are almost precisely those on which I have myself relied.

1 With Dible, I attach special importance to the presence or absence of muscle in the floor of the lesion. In all the early cancer cases and many of those which are fairly advanced a more or less continuous band of muscle is present. Even in advanced cases where the tumour has completely penetrated the stomach wall over large areas relics of the muscular coat persist every here and there in the midst of the neoplastic tissue in a way which is never seen in the floor of a definitely chronic ulcer.

2 Except for the rare instances of acute perforating ulcer, the depth to which the muscular coat is penetrated is a very fair index of the chronicity of a simple gastric ulcer, at least for the first two or three months. After that, in my experience, the muscular coat is invariably breached, its severed ends turning upwards towards the mucosal aspect. The floor of the ulcer is composed of a variable quantity of granulation and fibrous tissue, with a narrow or sometimes broad zone of sloughing on the surface, and it is the persistence of a portion of this densely fibrous floor, unpenetrated by cancer cells, which is one of the most valuable positive indications, in a case of cancer, that there has been pre-existent simple ulceration. Even sclerosing cancers of the stomach do not produce these large areas of cancer-cell free fibrous tissue, nor do I think that cancer cells readily penetrate the densely fibrous floor of such ulcers. On these points I find myself rather at variance with the views expressed by Dible.

3 The third point is the presence or absence of obliterative endarteritis and organized thrombo-phlebitis in the floor of the lesion. This also is a valuable criterion, inasmuch as these changes occur rarely, in my experience, in primary cancer, very commonly in simple chronic ulcers and their resulting scars.

Working on these criteria, it is possible to classify the clinical specimens which I have examined in the manner shown in the following table:

TABLE IV—*Analysis of 216 Clinical Specimens of Gastric Ulcer and Gastric Cancer*

Simple chronic ulcer alone	134
Cancer arising in chronic ulcer	14
Cancer alone	68
	216

In other words, 9.5 per cent of the cases of chronic ulcer had become cancerous, or, approaching from the other standpoint, 17 per cent of the cases of cancer had originated in a chronic ulcer.

[Professor Stewart showed on the lantern the actual sections from seven typical cases of ulcer-cancer and four of primary carcinoma to illustrate the points referred to.]

SECTION OF SURGERY

GENERAL DISCUSSION

Dr GARFONK COLF (New York), who was invited by the President to give the views of radiologists in America on the ulcer cancer theory, said that five years ago it was taught that 68 per cent of all his ulcer cases since 1910, however, gave the following figures. In approximately 10 per cent of cases it was difficult or impossible to state definitely from the radiological evidence alone whether the case was one of simple ulcer or of cancer when first seen, of the remaining 90 per cent, all of which were regarded as definite cases of simple ulcer, only one case subsequently developed cancer. He therefore regarded the evidence as being strongly contrary to the view that cancer was frequently a sequel of chronic gastric ulcer.

Mr JOHN MONLFY (Manchester) said that the view that cancer of the stomach commonly originated in a simple ulcer made a very strong appeal to the surgical mind. Amidst so much that was nebulous in the etiology of cancer various known irritants—chemical, mechanical, thermal, and radiatic—stood out as solid rocks of fact, and the argument by analogy was always a tempting one. The weight of powerful authority, both pathological and clinical, was behind the ulcer cancer theory. The pathologists of Mayo Clinic, Wilson and McCarty, had stated that 71 per cent of specimens of cancer of the stomach showed evidence of preceding ulcer, and that 68 per cent of apparently simple ulcers showed evidence of cancer on the clinical side, had said that Sir Berkeley Moynihan, on the other side, gave a previous history of a steady average of two out of three cases of cancer that he saw on the operating table gave a previous history strongly suggestive of ulcer. This view, if they could accept it, lent point to their advice that patients with gastric ulcer should submit to an early, direct, and radical surgical attack upon the ulcer.

On all these grounds it was a most attractive theory, but a careful and unbiased study of the cases at his disposal had led him quite definitely to the view that, attractive though the theory of origin in a simple ulcer might be, it was not true. The problem was both pathological and clinical, and could not be settled in one field to the exclusion of the other. If they accepted the figures of Wilson and McCarty, that 68 per cent of apparently simple chronic ulcers showed early carcinoma in their edges, and if they agreed that cancer of the stomach seldom ran a longer course than three years, or of ulcers treated by simple gastro-enterostomy, some 68 per cent of the patients would be dead of cancer in three years. But it was well known that such statistics did not tally with clinical experience, or with any published series of case records. How, then, were they to account for the views of these American investigators who claimed that gastric ulcer resulted in cancer with such alarming frequency?

The main fallacy underlying the claims of the ulcer-cancer school of pathologists would appear to be that they had interpreted certain irregularities in the gland tubules, and certain misplaced columns of cells often found at the edge of a chronic ulcer, as early cancer, when in reality they were distortion of the epithelium entangled in scar tissue, and were due to attempts at healing. This was the definite opinion of Sir Bernard Spilbury, and more recently Professor J. H. Dible, in a paper of great importance in the *British Journal of Surgery*, had given overwhelming evidence in favour of the same view. Professor Dible, in a consecutive series of 126 cases of simple chronic ulcers excised by various Manchester surgeons, found no single case of genuine cancer, though many of 33 cancers of the stomach examined, good evidence of preceding simple ulcer at the edge. He also found, in a series of 33 cancers of the stomach examined, good evidence of preceding simple ulcer in only two. Professor Stewart of Leeds, following another line of inquiry, had shown that the usual position of simple ulcers differed very materially from that of cancer of the stomach. On the clinical side, also, he believed that evidence was decidedly against the ulcer-cancer theory. His experience was that patients with proved cancer of the stomach gave on an average a little over twelve months' history of gastric symptoms before operation, whereas in

proved simple ulcer cases the characteristic symptom had been present for an average of over ten years. He found that, roughly, 70 per cent of cancer patients give a history of the classical symptoms coming on insidiously in middle life with no previous history of indigestion, while 30 per cent give a history of periodic attacks of gastric pain, generally over a period of two to five years, simulating ulcer at first, but later becoming continuous. This late change in the character of the symptoms was due, he believed, not to a change from a simple to a malignant ulcer, but to the onset of partial pyloric obstruction from a lesion which had been malignant from the first. There was a type of slow growing cancer of the stomach which before its symptoms with the failure to recognize the occurrence of this ulcer simulating cancer, simulated cancer. No surgeons to support the ulcer-cancer theory. The origin of benign stomach cancer was caused by an ulcer which had advanced to malignant changes in some cases, and commonly accepted that more often under six years in duration than over. If ulcer give rise to cancer with any frequency, surely the ulcers of longest standing, of which those causing hour glass stomachs were typical, should show the highest incidence of cancer. The fact that they did not do so, was important evidence against the ulcer cancer theory. He did not deny that a simple ulcer of the stomach might result in cancer, and he believed that occasionally that did happen. But when it happened it was a clinical and pathological curiosity, an event of such comparative rarity should not influence the unduly either in the diagnosis of gastric cancer or in the treatment of gastric ulcer.

Dr W. D. HIGGARD (Nashville, Tennessee, U.S.A.), after making a reference to the work of Dr. Goe on the etiology of carcinoma, said he regarded the clinical association of ulcer with carcinoma of the stomach as hopeful rather than the reverse, for with better means of diagnosis of ulcer, and earlier operation, the incidence of cancer of the stomach might be reduced. His own learning was strongly toward the ulcer cancer theory that he made it a routine practice to excise ulcers with the enteric and have them examined pathologically. He pointed out that the death rate among patients suffering from what was considered to be simple ulcer, and who had been treated by gastro-jejunostomy alone, was three times that of the normal population in the same age group, he regarded this as to some extent confirmatory of the ulcer cancer view. Among cases which were definitely cancerous he found 28 per cent of "five year cures" by gastrectomy.

Mr A. H. BRADSHAW (Manchester) said that once the diagnosis of cancer of the stomach was established as a reasonable probability the question of surgical measures at once arose. One should always aim at a radical operation, and the first question was present which part out of was whether any condition was present which put out of count any hope of a radical removal. Such contraindications might be explicable of discovery (a) before laparotomy or (b) only after the abdomen had been opened. Apart from conditions of a general and constitutional nature such as would preclude any severe operation, certain local conditions were definite contraindications (1) enlargement of the liver, especially if associated with a supracardiac nodules, (2) ascites of a degree sufficient to be detected clinically, (3) enlarged glands in the suprarenal regions, particularly on the left side, (4) secondary peritoneal deposits engorged by gravity, upon the pelvic peritoneum and detectable clinically on rectal examination. An enlargement of the recto-vesical pouch, a rectal examination should never be omitted when considering the feasibility of radical operation in any abdominal malignant

condition, and the detection of induration in the recto-vesical pouch would not infrequently prevent a useless operation, and (5) a mass palpable through the abdominal wall was frequently held to contraindicate radical measures, but need not necessarily do so. It depended more upon the question of fixity than palpability. A palpable mass, if fixed, would certainly prevent a radical operation, but not so if mobile. Contraindications to radical operation discoverable only after a laparotomy were: (1) small secondary deposits in the liver—these were detectable only when near the surface, (2) peritoneal deposits on the peritoneum of the recto-vesical (or recto-uterine) pouch too small to be felt per rectum, (3) secondary glandular deposits beyond reach of the operative field—at the hilum of liver, superior mesenteric, meso-colic, or lumbar glands, and (4) fixity of the stomach to other parts, especially liver and pancreas—such adhesion might be inflammatory only, and superficial slices might be removed from the liver and pancreas with the growth. If the transverse mesocolon was involved in the growth so that its removal would necessitate sacrifice of the middle colic artery, and, consequently, excision of a large part of the transverse colon, a radical operation, except in otherwise extremely favourable circumstances, should not be attempted. If, owing to the presence of any of these contraindications, radical extirpation was considered impossible, the next question to decide was whether a palliative operation was advisable. Gastro-enterostomy, except where the growth was near the pylorus and where pyloric obstruction was actually in existence or threatened to do so shortly, gave such a small measure of relief as to be scarcely worth performing. Any palliative operation for carcinoma other than in the pyloric portion should take the form of a partial gastrectomy, and, provided that the whole of the disease in the stomach could be removed, was well worth while undertaking, even though disease be left in the glands, peritoneum, or liver. The immediate results were often remarkably good, and there was always a chance that an error in the original diagnosis or in one's estimate of the extent of the disease might lead to a pleasant surprise in the form of a permanent cure.

If no contraindications were present radical extirpation should be attempted. A consideration of the lymphatic arrangements showed that the minimum amount of stomach to be removed was between a line continuing downwards the right edge of the oesophagus to the greater curvature and a line one inch beyond the pylorus—that is, the whole of the lesser and about one-half of the greater curvatures were removed. All operations of the type of Billroth No. 1 were, therefore, excluded, Schoemaker's operation was also unsuitable, since it left too much of the greater curvature. Only operations of the type of Billroth No. 2 or the Polya modification of it were worth of consideration. As regards the technical details of the operation, the incision should be ample to prevent much pulling about by retractors, a paramedian incision through the right rectus muscle was usually adopted, though where radiography showed the growth to be towards the cardiac end a left paramedian gave better access to the most difficult step of the operation—the satisfactory clearing of the upper end of the lesser curvature. When operating for carcinoma all the omentum corresponding to the part of the greater curvature excised should be completely removed, since it was not uncommon to find enlarged glands in the omentum some distance away from the greater curvature. This was best effected by making the first step of the operation the thorough separation of omentum from transverse colon so opening up widely the lesser peritoneal sac, as recommended by Pruchet. By gentle traction upwards on the omentum the stomach was steadied and the posterior surface of stomach and duodenum could be very readily freed by gauze stripping, while the arteries—pyloric, pancreaticoduodenal, or right gastro-epiploic—were readily exposed and secured at this stage. For the division of the duodenum he preferred Miles's crushing clamp, which crushed a portion about one inch wide, a ligature was passed and tied around each end of this crushed portion, which was then cut across just proximal to the distal ligature and the duodenal stump invaginated by two successive purse-string sutures. The lesser omentum was divided as close to the hilum of the liver as possible and the coronary artery secured near its

origin. For the division of the stomach he was at present using the three-bladed clamp of Dr de Martel. The divided end of the stomach was then anastomosed to the jejunum, preferably by the Moynihan-Balfour modification of the Polya operation, where the jejunum was brought around the splenic end of the transverse colon in a very short loop (three or four inches) and applied to the divided end of the stomach so that the proximal jejunum was attached to the greater curvature.

Dr F. N. G. STARR (Toronto) held that the surgery of the stomach had advanced so far that, given an early case of cancer, one might promise almost uniformly good results that were lasting. The unfortunate thing was that many such cases failed to seek advice until the disease was well advanced. When a patient presented himself with a history of some gastric disturbance, with loss of "pep" and loss of weight, it behooved them to hasten with their investigation in order to clear up the diagnosis as quickly as possible. They should not wait for pain, because pain, in his experience, was one of the later symptoms, and its presence usually meant that the growth had extended beyond the stomach, was no longer localized, and was in consequence no longer operable.

Mr GARNETT WRIGHT (Manchester) considered that the clinical evidence was all against the ulcer-cancer theory, and in his practice only 6 per cent of ulcer cases developed carcinoma.

Mr J. S. ROWLANDS (London) described a case of tuberculous ulceration of the stomach which so closely resembled a carcinomatous condition that the true diagnosis was only made when the ulcer was examined pathologically after a gastrectomy had been performed. He favoured an early exploration in cases where there was any suspicion of carcinoma. The operation of gastrectomy was not a dangerous one if the patient's vitality had not already been sapped by the disease. He preferred the ante-colic anastomosis when performing partial gastrectomy either for ulcer or for carcinoma, the jejunal loop should be short, but not so short as to constrict the transverse colon. It was important, he held, to remove the great omentum with the stomach. The danger of wounding the mid-colic artery had been much exaggerated, for he believed that the collateral circulation was quite sufficient to ensure the vitality of the gut.

Mr M. MAZOUZIAN (Ashton-under-Lyne) spoke of the value of local anaesthesia, and described a formidable operation performed by a Continental surgeon at which he had assisted. The operation, which amounted to a nearly total gastrectomy, together with removal of the transverse colon, necessitated by an injury to the mid-colic artery, occupied six hours. At the conclusion, the patient, who said he had felt no pain, was able to hold a conversation with the surgeon.

Mr H. S. SOUTER (London) believed in the value of operation, even in late cases, and gave two instances from his own practice. The first patient was explored for pyloric obstruction, and found to be "ludicrously inoperable." A gastro-enterostomy was performed, the stomach being placed in the one small unaffected portion of the stomach that was available. This patient was able to return to work for six months before he died. The second case was one of an extensive carcinoma of the stomach in a patient aged 26 for whom a resection was performed and life was prolonged by twelve months. Mr Souter concluded with a reference to the type of gastrectomy performed by Schoemaker which he considered excellent. It was possible by applying Schoemaker's clamp appropriately, to make the resection much more extensive than it appeared to be in the published description of Schoemaker's operation.

The PRESIDENT summed up the situation by saying that surgery had now outpaced medicine in the treatment of carcinoma of the stomach. There must be some morbidly attached to every surgical operation, but the mortality of partial gastrectomy was surprisingly small. In the operation for cancer of the stomach he did not regard it as necessary

to remove the whole of the great omentum, which could be put to the useful purpose of covering the operation field if retained. A modified Billroth I operation, while suitable for gastric ulcer, did not permit resection in carcinoma cases. He

performed a modified Polya operation with an intercolic no loop anastomosis between the jejunum and the whole cut edge of the stomach. He had never needed to reoperate for any complication following this operation. The preparation of patients for operation was most important. He advocated blood transfusion, heliotherapy (either artificial or real sunlight being used), and massive intravenous injections of glucose pushed to the point of producing diabetic coma, from which the patient was rescued with insulin. As very little further improvement could now be hoped for from advances in surgical technique there was a need for the education of the medical profession, and of the public at large, in order to bring about an earlier diagnosis. The Ministry of Health was likely to take this matter up in the near future.

SECTION OF LARYNGOLOGY, OTOTOLOGY, AND RHINOLOGY

ARTHUR H. CHEATLE, C.B.E., F.R.C.S., President

DISCUSSION ON OCCUPATIONAL DISEASES OF THE EAR, NOSE, AND THROAT, AND THEIR PREVENTION

OPENING PAPERS

I.—F. H. WESTMACOTT, C.B.E., F.R.C.S., B.Sc.,
Honorary Aurist and Laryngologist Manchester Royal Infirmary,
Lecturer in Laryngology Manchester University

INDUSTRIAL diseases have occupied the close attention of the Secretary of State from time to time since the introduction of the Workmen's Compensation Act in 1906, which included a list of industrial diseases in the third schedule, and which was extended by several Orders, including those of the years 1913-16, dated February 26th, 1918 (S.R. and O. No. 287), November 15th, 1921 (S.R. and O. No. 1786), December 31st, 1921 (S.R. and O. No. 2031), January 2nd, 1923 (S.R. and O. No. 6), January 16th, 1924 (S.R. and O. No. 20), all of which are consolidated in the recent Act of 1923.¹ There is therefore a definite list of diseases or injuries with a description of the process in which and by which they are incurred, with the result of causing incapacity of the worker from following his or her occupation for a definite period. As, however, workers may suffer from disease which cannot be definitely attributed to causes arising "in and out of" the occupation, but which are common to the population of the district, it is incumbent on the workman to prove that his incapacity is due to the disease which is included in the said schedule, and arising in the process described. There is, however, a provision in Section 8, para (10), which states that—

Nothing in this section shall affect the rights of a workman to recover compensation in respect of a disease to which this section does not apply if the disease is a personal injury by accident within the meaning of this Act.²

It is furthermore enacted in "Statutory Rules and Orders," 1918, No. 287, Master and Servant, Workmen's Compensation Industrial Disease,² Section 2

A person suffering from any of the diseases described in the schedule as dermatitis produced by dust or liquids ulceration of the skin produced by dust or liquids and ulceration of the mucous membrane of the nose or mouth produced by dust, shall not be entitled to compensation under the provisions of the said section on account of the said disease if he is disabled only for employment in the particular process in which the disease has been contracted. (Third Schedule 11 (c) Ulceration of the mucous membrane of the nose or mouth produced by dust.)

Thus it is observed that should a workman be incapacitated for his occupation in the process detailed in the schedule and be fit to work in any other occupation and earn his former wages, his entitlement to compensation from his employer ceases. The most frequent illustration, perhaps, of this principle at the present time is the example

of "baker's dermatitis," which recurs after healing on resumption of baking, and yet the workman is fit to carry on any other employment. This may arise in any affliction of ear, nose, or throat.

The subject of occupational diseases of the ear, throat and nose may most conveniently be discussed under two headings:

(1) Industrial diseases which are included in Schedule 3 of the Act of 1903 extended by various orders, and included in the Act of 1923.

(2) Industrial diseases which are met with in workers which are not so included and may or may not cause incapacity of employment.

In the first category a list of the diseases and description of the process which have reference to afflictions of the ear, nose, and throat, under the numeral shown in the list is as follows:

Schedule 3

Description of Disease or Injury	Description of Process
1 Anthrax	Handling of wool hair, bristles, hides and skins
2 Lead poisoning or its sequelae	Handling of lead or its preparations or compounds
3 Mercury poisoning or its sequelae	Any process involving the use of mercury or its preparations or compounds
4 Phosphorus poisoning or its sequelae	Any process involving the use of phosphorus or its preparations or compounds
5 Arsenic poisoning or its sequelae	Handling of arsenic or its preparations or compounds
<i>Extension of Schedule 3</i>	
5 Poisoning by nitrous fumes or their sequelae	Any process in which nitrous fumes are evolved
11 (c) Ulceration of the mucous membrane of the nose or mouth produced by dust	
13 Chronic ulceration or its sequelae	Any process involving the use of chromic acid or bichromate of ammonium, potassium, or sodium, or their preparations
15 Compressed air illness or its sequelae	Any process carried on in compressed air
22 Glanders	Care of any equine animal suffering from glanders handling the carcasses of such animal

It will be observed that No. 11 of the list above—which includes (a) dermatitis produced by dust or liquids (b) ulceration of the skin produced by dust or liquids—does not lay down any specified process, and is applicable to any occupation, indoor or outdoor. Experience shows, however, that it is very exceptional to find any cases arising under this category, owing to the fact that no incapacity is caused by the disease. In the second group of diseases which affect workers, not included in the list of specified diseases and occupations, there are many which deserve more thorough and extended observation and research to determine how far such diseases are due primarily to conditions of occupation, and how far they are due to local climatic or hygienic conditions of life of the town or district. Much work in examination of individuals in factories and workshops, dwellings, clothing, and habits, needs to be done before any valuable opinion can be formed as to the influence of the occupation on the individual or the disease. An extended investigation of the literature on the subject has failed to provide any matter upon which a definite statement can be made, although departmental committees have often been set up to hear medical evidence in support of or against inclusion of a disease or diseases under the provisions of the Act. I need only refer you to the able disquisition of Dr. Edgar L. Collis, H.M. Medical Inspector of Factories, in his Milroy Lectures (1915)³ on "Industrial pneumoconiosis, with special reference to dust phthisis." The difficulty is further appreciated when divergence of medical opinion is expressed by able practitioners of long experience in industrial districts and whose professional work has very largely in dealing with workpeople in factories and workshops. Nothing exemplifies this better than the Report to the Home Office and to the Local Government Board upon an inquiry into the alleged danger

of the transmission of certain diseases from person to person in weaving sheds by means of "shuttle-kissing," in which the evidence of fifty-eight Lancashire medical officers of health is given in replies to a circular letter addressed to them by the Local Government Board in 1911. The report further demonstrates the difficulties of deep inquiry into the history of cases and the great amount of time required to establish with any certainty the incidence of the disease to any process of the industry or even to its aggravation. This is the reason why the inclusion of many affections has been rejected by the courts of inquiry held.

It is proposed to discuss the occupational diseases which are scheduled under the Workmen's Compensation Acts first of all, because of their definite position, and to deal afterwards with the others. It is convenient to follow the list scheduled in the Act, and to deal only with such signs and symptoms as are applicable to the particular organs in the regions of the ear, nose, and throat, but it must be appreciated that in the majority of cases the disease or injury is not limited to those parts, but affects in even a wider degree the skin surface of the body, or the lungs, if not other organs. A further point to be considered is that incapacity is, in most cases, not produced by the local affection but by its wider extent.

Anthrax

In the handling of wool, hair, bristles, hides, and skins, anthrax is contracted by workmen employed in (a) Dealing with live animals suffering from anthrax, such as drovers, shepherds, farmers, veterinary surgeons, etc. (b) Those who touch the carcasses of animals which have died from anthrax, such as slaughterers and butchers. (c) Those who handle skins or offal of diseased animals, such as felle-mongers, tanners, wool or hair workers, plasterers, felt makers, brush and mattress makers. (d) Transference from one human being to another. It is said to be probable that those who eat very little animal food are most susceptible to the disease.

The disease appears in more than 99 per cent of the cases on exposed parts, such as the hands, face, neck, or chest. When the disease is on the neck, within two or three days the swelling may involve the larynx or mediastinal glands as well as the cervical glands, producing difficulty of breathing and swallowing, and fluids swallowed may return through the nose. In such cases a fatal result in 40 per cent of cases has been recorded chiefly at Guy's Hospital between 1873 and 1893. It is rare, however, to find affection of the larynx or mouth, compared with the instance of lung infection. Prevention can only be carried out by either prohibiting importation of foreign hides or those of suspicious origin or conditions, or by sterilizing the hair before or during manufacture.

Lead Poisoning or its Sequelae

Apart from the general manifestations of acute or chronic plumbism the only symptoms of any moment are the neuritis of the auditory nerve and acute labyrinthitis with Meniere's symptom complex, which have been observed by myself in three or four workers. The symptoms subsided in all but one case, so far as they could be traced. There is little doubt that alcohol indulgence had an influence, and possibly syphilis in the permanent case. Paralysis of laryngeal muscles occurs in some cases. Tanquerel¹ called attention to aphonia in horses in lead works, neck-sitting tracheotomy, and Syjous² described adductor paralysis in a house painter. Unilateral paralysis of the adductors in persons suffering from plumbism was described by Moir³ Mackenzie,⁴ whilst Sieret⁵ records a curious case in which paralysis of the transverse and oblique arytenoid muscles prevented approximation of the posterior ends of the vocal cords. Also a second case of paralysis of the posterior crico-arytenoid muscles on both sides, the adductors remaining unaffected. Sensory disturbances of taste and smell are unusual, except in general nerve paralysis and mental changes.

Mercury Poisoning or its Sequelae

Under this heading is included any process involving the use of mercury or its compounds or preparations. The

dangers of mercurial poisoning in this country arise chiefly in the manufacture of barometers, thermometers, and electrical meters, in gilding and silvering generally known as "water gilding," in chemical works making corrosive sublimate, vermilion or red oxide of mercury, in hatters' and furriers' workshops, the manufacture of hard felt hats, from utilization of the crocted rabbit fur, in print and colour works, in the manufacture of surgical dressings containing salts such as cyanide and perchloride of mercury, etc.⁶ Mercury gives off vapour to a certain extent even at ordinary temperatures, but warmth increases this tendency. When the metal, as distinguished from its salts, is used, the danger of poisoning arises chiefly from inhalation of the vapour, and in a minor degree from swallowing or from absorption by the skin. In the case of mercurial salts it is by swallowing.

The symptoms are those familiarly known to all in the administration of the drug for syphilis. Locally it is manifested by a bluish line on the gums similar to that seen in lead absorption. Sometimes the tonsils and pharynx become involved in the inflammatory processes affecting the mouth. The important point in most patients, and especially those engaged in the hatters' and furriers' process exposed to the fumes of mercuric nitrate, is the condition of the teeth. The typical appearance in the teeth of these workers for years in "crocting" is loss of the molar teeth in both jaws. The upper incisor and canine teeth are frequently absent, and what teeth remain are blackened and loose. They show a marked tendency to erosion, principally of the enamel, and distinct from caries when the dentine suffers. The gums recede and the anterior surfaces of the roots become exposed. Inflammation of the nasal and laryngeal mucous membrane is associated with conjunctivitis and dermatitis.

The best means of prevention is frequent examination and careful cleaning and repair of the teeth. When the teeth are quite sound the symptoms of mercurial poisoning are exceptional. An important symptom of chronic mercurial poisoning is the implication of the nervous system which is not infrequently manifested by deafness with Meniere's syndrome in addition to tremors and muscular weakness. This is not uncommon in hatters' and furriers' workshops, and hard felt hat makers. Cases have been observed for years, and although treatment has in some instances enabled the worker to continue his occupation in others the symptoms have remained after cessation of handling the dangerous materials.

Phosphorus Poisoning or its Sequelae

The disease commonly known as "phossy jaw"—necrosis of the jaws due to absorption of phosphorus used in the manufacture of matches—is rarely met with at the present time owing to the prohibition of its use by Government in all countries where public health legislation exists. It is really now of historic interest only. It chiefly occurred in persons employed as "mixers" or "dippers," arising from the phosphorus fumes gaining access to carious teeth in the upper and lower jaws the latter being more often affected, this is the only mode of entrance. The process commences by setting up periodontitis and periostitis, followed by necrosis. In cases of superior maxillary infection the other bones of the face and skull may become involved, as well as the meninges and brain causing danger to life. The affected teeth fall out or are removed by operation after becoming loosened, persons with good teeth are not affected. When the disease is started severe pain and swelling of the alveolus supervenes, necessitating surgical intervention.

The course of the disease is very gradual taking from two to five years. Prevention consists of careful cleansing of the teeth, regular inspection and the use of a carbolic or sodium phenate mouth wash. The hands are to be carefully washed before eating meals, which must be taken outside the factory. Improved ventilation, wearing of respirators and the substitution of the less dangerous forms of phosphorus together with exclusion of workers with bad teeth from the industry, have prevented its occurrence.

Arsenic Poisoning or its Sequelae

Disease due to the handling of arsenic, its preparations, or compounds occurs chiefly as a result of (1) inhalation of, or contact with, the dust of salts of arsenic, and (2) inhalation of arseniuretted hydrogen gas. The symptoms exhibited locally are hoarseness, with soreness and dryness of the mouth and throat, in addition to conjunctivitis. The characteristic lesion produced on the upper air passages by salts of arsenic, in the form of dust, is perforation of the nasal septum, which is rapid—it may be in the course of one month from the commencement of work.¹⁰ The perforation may be small or large, but the anterior and lower borders are never involved, so that no bone is attacked and nasal deformity is not induced.

The salts of arsenic act as an irritant or an escharotic on the mucous membrane, whilst arseniuretted hydrogen acts haemolytically, pure metallic arsenic is innocuous. When once the perforation is complete and its edges healed no further discomforts are experienced, indeed, some workers do not even know of the existence of the condition. Prevention of disease is not possible so long as hand labour is employed in the manufacture of arsenical compounds, even with regular medical inspection, protective respirators and garments, together with exhaust ventilation. Instances of suppurative nasopharyngitis and suppurative otitis media have been reported. In a case of chronic arsenical poisoning recorded by Lewin, an inflammation of the internal ear followed arsenical poisoning in the nasopharynx and middle ear.

Poisoning by Nitrous Fumes or its Sequelae

The effect of nitrous fumes is to set up an oedematous inflammation of the mucous membrane of the respiratory tract, more particularly of the larynx, trachea, and bronchi. Death may ensue in a few moments or hours.

Dermatitis Produced by Dust or Liquids

Diffuse dermatitis, eczema, and furunculosis are produced in workers in zinc ore containing also lead, cadmium, and arsenic, which has an irritating effect. Wood polishers and jig-saws, who use denatured alcohol, are similarly affected. Eczema of the auricle and external auditory meatus, due to dust and grime, is met with in workers in metal, glass, stone, and wood, grinders, polishers, mother-of-pearl cutters, and brushmakers. Dermatitis, with or without burns on the hands and wrists, due to extreme heat, is met with in stokers and firemen, smelters, braziers, and puddlers, and in many cases it is followed by deformity, it would be admissible under Section 8, para 10.

Ulceration of the Mucous Membrane of the Nose or Mouth Produced by Dust

Any industrial process giving rise to dust is held to be responsible for incapacity of the worker, and a very large field is opened up, considerable doubt may arise as to the active agent. In some instances irritant metallic particles are present in the air of the workroom, or vapours containing soluble or semi-soluble salts or other matter suspended in them produce the same result. In a dried air penetrating particles are productive of a more irritating effect. Of metallic particles the most pronounced are silicates of copper or zinc, siliceous quartz, slate rock, and arsenical ores. The incidence of chronic catarrh and suppurative disease of the nose, nasopharynx, and pharynx, Eustachian tubes, and middle ear, is favoured in workers in close relation to machinery, especially irritating quality and as metal burnishing, glass grinding, mother-of-pearl cutters, lime burning, fertilizer mixing and packing, it is also encountered in trades dealing with wool, hair, and grass sorting, and jute and hemp spinning. Unless the inflammatory process goes on to actual ulceration a claim under the Act could not be upheld except under Section 8, para 10. In mercury mining the initial symptoms occur more commonly in the mouth, but in some cases there is acute labyrinthitis and Meniere's symptom complex. Inflammation of the nasal mucous membrane, with or without perforation of the septum, is met with, not only in those engaged in handling arsenical preparations, but also in workers in hygroscopic salts, such as sodium chloride and

the chlorides of calcium and magnesium. Jegge¹¹ quotes Muller, who examined 165 salt grinders and pickers, and found that 45 had catarrh of the nasal mucous membrane and 42 perforations of the nasal septum. Cement dust exerts nearly all its effect on the upper air passages, leaving the lung tissue unaffected.

The effect of dust inhalation is to produce hyperemia of the blood vessels, and frequently an eczematous condition round the rhina. Chronic nasal catarrh comes on later, possibly after several years, and finally atrophy with pallor of the mucous membrane and loss of the vibrissae. In the majority of cases, however, which have been observed in South Lancashire, the condition of chronic hypertrophic rhinitis, giving rise to nasal obstruction and mouth breathing, is the disability presented by patients in the outpatient departments of the hospitals, much depends on the atmosphere and climate, and it is considered that the humidity of this industrial area is responsible for the hypertrophic rather than the atrophic state. Occupations such as fun-pulling, cotton-waste sorting, flannelette raising and all kinds of polishing operations on a wheel, produce similar pathological changes. The harder and more gritty the particles the more rapidly and surely will the condition be produced.

Collis,¹ who examined thousands of grinders and granite cutters and others exposed to dust, states that the lining membrane of the nose for the anterior quarter of an inch is smooth and dry and pale in colour, behind this the membrane, which is probably covered with a crust of dust, is red and inflamed. Dust is also seen on the pillars of the fauces, and on the back of the pharynx, which is insensitive to the touch of a spatula. The reaction is first mechanical, repeated irritation and the pressure caused by the deposit of dust on the septum leads to ulceration and perforation. This process extends by continuity of tissue up the Eustachian tube to the middle ear, causing deafness. Inhalation of lime dust in unloading cargoes such as coloured sphatite ores, gives rise to severe inflammation of the lining membrane of the nose, and also to small ulcers on the mucous membrane of the buccal cavity.

Mycosis of the External Auditory Meatus (Otitis Externa)

This occurs in weavers, spinners, wool sorters, paper mill tenders, laundry workers, and dust workers. The growth of spores is favoured by an oily or fatty soil together with a warm atmosphere. Repeated attacks cause thickening of the dermoid coat of the membrana tympani and so impaired hearing. A heated ear impregnated with dust and foul gases affects the ear by extension from the nose and nasopharynx. There may be a chronic non-suppurative progressive thickening of the soft tissues of the middle ear or a more or less destructive suppuration of the middle ear tract.

Preventive measures in all dust diseases have been successfully undertaken by means of exhaust ventilation in shops and factories, producing a marked change in the worker's occupation. This ventilation consists, not only in removing the foul air from the building, but special fans are provided also for each machine used. Respirators have been found ineffective for long continued use, on account of interference of breathing by fouling and the great difficulty in keeping them clean. The factories and workshops of Lancashire are now in such a well constructed and organized state that the health of industrial workers compares very favourably with any occupation in this country. Incapacity from the various industrial diseases is limited to isolated cases, as the records of insurance companies dealing with workmen's compensation abundantly prove.

Chronic Ulceration or its Sequelae

This is one of the important industrial diseases which affects a large proportion of the workers but which causes little or no incapacity. The Departmental Committee on Compensation for Industrial Diseases, in its report in 1907, states, under para 15, Chronic Ulceration

"Where in the manufacture of the crystals dust is inhaled, the septum of the nose generally becomes perforated but during the months that this process of ulceration takes before it is completed

there is no evidence that the pain or inconvenience is ever such as to cause incapacity for a week. The lesion can be distinguished without difficulty. The affection arises directly from the employment and we recommend that it should be added to the schedule."

Chromic acid and the bichromates of potassium and sodium cause erosion of the septum of the nose from inhalation of the dust, but as dust is given off only in the manufacture of potassium bichromate, perforation of the nasal septum is limited to the workers in such factories. Legge examined 198 out of 743 workers employed in such factories, and discovered 145 (73.7 per cent) with the septum either ulcerated or perforated. The perforation occurred in some cases within a few weeks of commencement of employment.

Bichromates are used in the following trades and crafts:

1. Ais. Chrome yellows, oranges, and reds, and by interaction with a solution of lead acetate, in which a risk of plumbism is added.

2. Dyeing and calico printing.
3. Photography and litho etching.
4. Oxidizing agent for coal tar colours.
5. Tanning by the "two bath" process. (The "one bath" process is not so dangerous, as the basic chrome salts only are used such as chrome alum. In the two-bath process, the hides are first treated with chromic acid, this is the dangerous stage. The second bath is a slightly acid solution of sodium thiosulphate. Sodium hyposulphite is useful in the treatment of "chrome holes" in the skin, and hence men are removed from working on the first bath to work on the second. It is rare to find an unbroken skin being affected by chrome, on the other hand, chrome dust will attack and ulcerate the nasal mucous membrane.)
6. French polishing.
7. Manufacture of safety matches, coloured glass, and porcelain.

In 1899 Legge¹² examined 176 men, of whom 126 had perforation of the septum and 26 had ulceration, probably a stage preceding perforation. Nearly all the men employed in the crystal department or furnaces had perforation. It usually appears in six to twelve months after starting work, in one instance it appeared in seven weeks, in two others in less than twelve weeks. The usual situation of ulceration or perforation of the nasal septum is a point a quarter of an inch from the lower edge of the septum and a short distance from its anterior limit. It is rather anterior to the so-called Zuckerkandl area, but it may encroach upon it, and, eroding the septal artery, set up severe epistaxis. Owing to the inspiratory tract it tends to spread upwards and backwards. Deprived of its mucoparichondrial blood supply the cartilage becomes necrosed, the process is arrested at the margin of the bony septum, and, as the anterior border recedes, no external deformity results. The appearance of a healed perforation is an oval with a smooth white scar edge of regular continuity. The affection commences with irritation of the mucous membrane, congestion, and free mucous discharge, accompanied by attacks of sneezing without pain. This is followed by thicker plugs of mucus in the nasal passages with more or less crust formation. The removal of these with the finger-nail assists in the rapidity with which necrosis and perforation ensues. Occasionally mucous patches without ulceration are seen on the pharynx, tonsils, and soft palate.

Prevention is not entirely possible, but exhaust fans and elaborate systems of ventilation have proved very successful. No constitutional effects have been found from chrome poisoning. Chrome ulceration has been notifiable under Section 73 of the Factory and Workshop Act, 1901, since January, 1920, and in the years 1920-22 197 cases have been notified, of which 100 came from bichromate factories, 83 from dyeworks, 9 from tanneries, and 7 from other industries.

Compressed Air Illness or its Sequelae

This clause in the schedule comprises cases of workmen who are affected by rapid or gradual increase or decrease of atmospheric pressure, such as caisson workers, divers, and aviators. The more rapid the change of pressure the more marked are the symptoms, which consist of reflex nausea and vomiting, vertigo and tinnitus. It is more marked during decompression, and particularly if there is Eustachian obstruction, although the symptoms are manifested during or after decompression, they are probably induced during compression by increase of positive pressure on the membrana tympani, fenestra rotunda and ovalis, raising the blood pressure in the vessels of the middle ear and labyrinth with extravasation of serum or blood. This

may destroy the terminal fibres of the auditory nerves in the cochlea and cause permanent deafness. On decompression gas is liberated in the blood vessels and may give rise to air emboli, or a similar action may take place in the perilymph or endolymph. Inflammatory conditions of the middle ear track and Eustachian tubes will magnify the symptoms and prevent also the opening of the tubes by the act of swallowing.

The objective signs are serous or haemorrhagic bullae on the tympanic membrane, which is rarely ruptured. Similar conditions are met with in bell divers and submarine workmen in diving suits. Aviators rapidly changing altitude are subject to the same changes in the middle ear and labyrinth which are characterized by the variable subjective noises experienced. When the pressure is stationary disturbances of the organ of hearing are not noticed. The symptoms usually pass off, with restoration of hearing, within a few days, but if a haemorrhage has occurred or the terminal nerve endings are damaged the deafness will be permanent.

Glanders

Care of any equine animal suffering from glanders, and handling of the carcass of such animal, tends to cause glanders, which may affect men in the form of a chronic form with skin eruption and nasal discharge which contains the *Bacillus mallei*. Knockers who deal only with the carcasses of glandered animals rarely contract the disease because the bacilli are practically confined to the lesions and the discharges from them.¹⁴

The second group of occupational diseases not scheduled under the Workmen's Compensation Act are such as are not considered to be capable of incapacitating the worker from following the employment, although if any personal accident could be proved a claim under Section 8, para (10), could be established.

Ear Diseases

Inflammation of the middle followed by slough and necrosis occurs in cold-storage workers. In rupture of the membrana tympani due to explosions in mining, blasting, tunnelling, or gun-firing tests the membrane usually ruptures along the line of the malleus. The edges are irregular, there is free bleeding, and speedy repair. The concussion causes a damage to the nerve endings, either functional or by extravasation of serum or blood, giving rise to deafness and vertigo. In the functional cases recovery follows more or less completely, but in apoplexy the hearing is permanently impaired or lost. In continuous noises, such as riveting in boiler-making or loud machinery, which gives rise to continuous nerve strain, deafness is due not so much to damage to the sound-conducting mechanism as to destruction of the sensitive nerve endings which constitute the sound-perceiving apparatus. More severe deafness is produced by intense sounds made up largely of overtones of high pitch than by noises of lower pitch such as are heard in cotton mills, etc. Tinnitus is invariable, but vertigo is only present in direct proportion to the loss of perception of the upper tone limit. Vertigo is more frequent also when vibration is present in machinery as well as noise.

Dr Thomas Barr of Glasgow, as a result of the examination of a large number of boiler-makers, concludes as follows:

- (1) No one engaged in boiler making for any length of time escapes impairment of hearing.
- (2) In about half the number of boiler makers the hearing power is so defective that the tick of a watch which should be heard 36 inches from the ear is either not heard at all or only in contact with the ear.
- (3) Three-quarters of their number either could not hear at all at a public meeting or could hear with difficulty.

It should be added that these workers can hear fairly well when talking in the noise in which they work. Barr and others are satisfied that long continued exposure to noise causes the delicate structures of the perceiving apparatus in the internal ear to lose its power of conveying impressions to the brain. The proof is that air conduction is better than bone conduction. The sensory apparatus, for high-pitched notes especially, becomes abnormally lost. Prevention has been directed to plugging the external auditory meatus. Telephone operators are subject to similar symptoms, induced by constant irritation of

the perception apparatus by the instruments or by loud cracking noises due to thunderstorms or intense electrical discharges in the installation.

Holt states that changes in the middle ear and sound-transmitting apparatus are mainly the cause of impaired hearing. Gadenigo makes three differentiations: (a) labyrinthitis without otitis media, (b) chronic extralabyrinthine otitis media with labyrinthitis, (c) chronic advanced otitis media with labyrinthitis, with vertigo as accompanying symptom. Ropke describes it as a combination of labyrinthine disturbance and a extralabyrinthine process in the middle ear. Urbantschitsch reports a case in which concussion of the labyrinth was accompanied by contraction of the intrinsic muscles of the middle ear.

The mass of evidence favours the view that the principal channel through which the internal ear is injured is through the sound transmitting apparatus of the middle ear and not through other bodily channels. Tones of medium low pitch readily transmitted by bone conduction are not a cause of impaired hearing. High pitched sounds are only transmitted because the passage of their short wave-lengths is obstructed by the soft body tissues. It is observed that only the ear exposed to loud sounds is affected. On examination the membrana tympani is found to be retracted, owing to contraction of the tensor tympani muscle. The tympanic mucosa is also thickened.

The sort of damage produced by sounds on the hearing apparatus has been the subject of controversy. Some support the theory that it is in the brain centres, while others maintain that the excessive stimuli expend their energy on the particular areas of the organ of Corti as exhibited by atrophic changes limited to certain areas of the basilar membrane with a point of maximum intensity corresponding to the maximum amplitude of stimuli. Gair supports this view and states that even a pure tone represents roughly an octave, so that a wide area may be found to be atrophic.

It is further added that no changes have been observed in the trunk of the auditory nerve and it is unlikely that central degeneration can have occurred.

The atrophic areas being limited to certain sounds, it is possible that normal areas will respond to higher or lower stimuli, as is found in clinical observations, until long-continued irritation over several years brings about gradually ascending and descending changes, till complete deafness results.

Throat Diseases

Acute or oedematous laryngitis may be directly caused by inhalation of irritant fumes of chlorine, bromine, iodine, ammonia, or sulphuric acid.

Membranous laryngitis, non-diphtheritic, occurs in workers in boiling steam or irritating vapours, such as in stokers and cooks.

Chronic laryngitis is found among professional voice users, or street callers, from misuse or faulty voice production.

Hypertrophic laryngitis is frequent in street hawkers, salesmen, or those exposed to dusty occupations, such cases may develop into pachydermia laryngis. Influenza in horses may convey the disease to those in charge of them. In a recent case under my care oedematous laryngitis was set up, with high temperature and death within three days.

Tuberculous laryngitis has been considered to be caused by dust acting directly on the mucosa and causing irritation in wool workers,¹⁵ but it has not been satisfactorily established whether it is a direct infection or through the blood or lymphatic system.

Extrinsic carcinoma of the larynx has recently been made the subject of a claim (on the ground of dust irritation) on behalf of a cotton-spinner who died from the disease. The claim was rejected, but was prompted, no doubt, by the recent successful arbitration on the subject of mule-spinners' epithelioma of the scrotum.

There can be no doubt that a comprehensive view of our industrial occupations at the present time will be convincing of the fact that the health of the worker has very much improved under the beneficent influence of the Factory Acts, the scientific methods of improved hygiene in construction of buildings and appliances to prevent well known evils, as well as the supervision of factory surgeons

and the establishment of welfare organizations in industries, combined with a higher standard of intelligence of the worker in the principles of personal hygiene.

II—S. W. GRIMWADE, O.B.E., M.B., Surgeon Commander R.N.

It is a fair statement to make that occupational diseases of the ear, nose, and throat are not common in the navy, in point of fact, they are almost entirely limited to diseases of the ear. There is undoubtedly a widespread opinion among officers and men in the service that they are liable to suffer from "gun deafness." It is important clearly to define what is meant by this. Is it a middle-ear or internal ear type of deafness?

Noise deafness as met with in boiler-makers and riveters is essentially a labyrinthine deafness, and it might be supposed that men who are frequently exposed to the detonations of guns would suffer from this type of deafness. Between December, 1921, and December, 1924, at the Royal Naval Hospital, Plymouth, 167 ratings were invalided from the service on account of deafness. This is a period shortly following the termination of the great war, and therefore likely to show cases whose hearing had been affected during the war, which might have been expected to show further deterioration. Of these 167 ratings, 74 per cent were suffering from suppurative middle ear disease, 17 per cent from chronic middle ear catarrh, and only 3 per cent from diseases of the ear directly attributable to the service—namely, traumatic rupture of the tympanic membrane and labyrinthine deafness.

During nearly two years' service at the Royal Naval Hospital, Plymouth, I have seen only four cases of labyrinthine deafness from gunnery practices, these all showed a very marked degree of deafness, which was temporary only and rapidly returned to normal, and only one case of labyrinthine deafness.

Inquiries were made as to the type of deafness found in ratings serving in H.M.S. *Excellent*, the Naval Gunner School, these patients were treated at the Royal Naval Hospital, Haslemere. I was informed that 99 per cent of cases were due to suppurative middle ear conditions, or applicable to occupational diseases, the statistics and conclusions of Got, otologist in the French army in 1915, are interesting. They are published in the *Revue d'Otologie*, January, 1916. He asks, "Who are the subjects most frequently attacked?" He found that those straining with healthy ears were more often injured in their labyrinth than those with defective ears. Of 283 patients with traumatic labyrinthitis, 144 (50.8 per cent) had no objective lesions of the middle ear, 74 (26.14 per cent) had objective lesions, but these arose at the same time as the labyrinthine lesions, and only 65 (22.9 per cent) had defects of the middle ear antecedent to the war. These statistics clearly indicate that true gun deafness or "noise deafness" is uncommon in the navy.

As to prevention, the common means adopted is the supply of cotton-wool for use as a plug in the external meatus. This is served out before all gunnery practices in H.M. ships, and although its use is not compulsory there is no doubt that it is commonly used. It has the disadvantage of making the user quite materially deaf. The Milloch-Armstrong mental plug is used frequently by officers, and has been of considerable value in reducing the shock of the detonation. Ordinary conversation can be heard quite readily while the plugs are being worn. Divers and players of wind instruments in the bands of the Royal Marines occasionally report themselves complaining of deafness, the cases I have seen are of the middle-ear type. It is associated with Eustachian obstruction and nasal conditions favorable to Eustachian catarrh.

The common type of deafness in the naval service is undoubtedly the middle-ear type, and although a proportion may be due to suppuration following traumatic rupture of the tympanic membrane, the vast majority of cases are due to previous middle-ear disease which has been quiescent for some years and is then reawakened by external inflammatory affections of the nose and nasopharynx.

There is no question that more careful examination of recruits for old middle-ear disease and for affections of the nose and nasopharynx would eliminate a large number of cases of potential deafness, and avoid the necessity of invaliding many fully trained seamen after four or five years' service. It would also prevent an element of malingering which does exist, and reduce the number of claims for compensation for impairment of hearing, alleged to have been caused essentially by their occupation in the service, many of them made quite honestly and in good faith, though ignorantly.

III—Wing Commander D RANKEN, R A F M S

I propose to confine myself to those diseases of the nose, throat, and ear especially associated with aviation as an occupation. Such diseases arise in the aviator for three main reasons: first, he works in an environment where rapid changes of barometric pressure are a constant factor, secondly, he may have conditions of the upper respiratory tract which cause symptoms, apparently trifling in importance at sea-level, but considerably aggravated at high altitudes, thirdly, he is continuously exposed to the noises of powerful motor engines and their exhausts.

The first and second of these causes are so closely interwoven that I intend to consider them together. We find in the Air Force that the effects of nasal obstruction, though disagreeable enough on the ground, are intensified in the air. Mouth-breathing, the result of nasal obstruction, may start or aggravate gingivitis or pyorrhoecia, especially when the inspired air is cold and dry, as occurs at high altitudes. Pyorrhoecia in its turn accelerates the onset of flying stress, and may bring about staleness, the cause of this may be confounded with excessive flying, overwork, worry, or lack of exercise. Laryngitis and tonsillitis are other sequelae of mouth-breathing in aviators, the engorged nasal mucous membrane associated with altitude frequently gives rise to insufficient ventilation and drainage of the frontal sinuses, and pilots often complain of headaches of varying duration during or immediately after descent. Most important, however, in this connection is the presence or absence of Eustachian obstruction, and I would like to speak in rather more detail on this matter. In flying, particularly in high flying and in rapid descents therefrom, it is important that the aviator should accommodate himself to and regularize the unequal pressures that may arise on either side of the drums. Any external condition or congestion of the Eustachian tubes will make this difficult or impossible. In consequence, if equalization by means of swallowing or auto-inflation is not or cannot be made during a rapid descent, the drums may become congested, invaded, or even ruptured, and pain and deafness, together with such effects of increased labyrinthine pressure as vertigo, nausea, or even fainting, may occur. Such symptoms have also been noted where unilateral Eustachian obstruction alone is present.

You will readily understand, therefore, the importance to the aviator and his passengers of adequate ventilation and drainage of the middle ears through the Eustachian tubes under rapidly varying degrees of atmospheric pressure. Broadly speaking, any condition of the nose and throat causing or likely to cause pharyngeal catarrh or inflammation is a potential factor in the causation of Eustachian obstruction. Such conditions are deflected septum, the various types of rhinitis, accessory sinus disease, unhealthy tonsils, adenoids, and any infectious catarrh of the nose or throat. Mouth-breathing, as also excessive smoking and drinking, are other predisposing causes. Free nasal respiration, a healthy upper respiratory tract, and satisfactory hygienic conditions of life are essential to the flying officer, and if one of the above-mentioned pathological conditions be present it should be corrected.

Passing now to the effects of noise on the aviator, there is, first, the deafness affecting pilots and observers, wholly due to the sharp reiterated crack of the exhaust. This is always of a temporary nature, and often lasts for several hours after a flight, the time depending as a rule upon the length of the flight. It is not due to changes in atmospheric pressure, presuming normal Eustachian tubes, and never occurs during or after decompression in a low-pressure chamber. Secondly, there is the deafness affecting those employed in testing aeroplane engines, this also is usually temporary in nature, the men on the work being only exposed to extreme noise for short intervals every day with frequent changes.

With respect to prophylaxis we have two methods of preventing aeroplane deafness. First, by cutting off or damping down harmful sound waves at their source by the fitting of silencers on exhausts or the leading of outlet pipes away from the pilot and observer, both are often matters of considerable technical difficulty. Secondly, we may protect the persons exposed to noise by some device designed to prevent sound waves stimulating the cochlear nerves and their filaments. For this purpose ear protectors of various types are sometimes used, many being based on the principle of a "baffle system." Cotton-wool lubricated with oil or glycerine is simple and often effective, and may be combined with pads sewn on the inside of well-fitting helmet ear flaps and pressing on the tragi. Precautionary measures to be adopted for those employed in testing aeroplane engines are (1) a special preliminary nose, throat, and ear examination and the non-employment on noisy work of men whose hearing is already affected, (2) periodical examinations with regard to depreciation of hearing, (3) shorter shifts on the noisy jobs. Proper hygiene of the nose and throat on general medical and surgical lines is essential where the deafness is not solely due to noise, but also to affections or irritation of the upper respiratory tract.

May I, in conclusion, say a few words on vestibular stability and the occurrence of vertigo in aviators. In this country we have never attached great importance to the supposed "motion sensing functions" of the vestibular apparatus, we are alive, however, to the value of a history suggestive of hyperexcitability of the labyrinth, and consider significant the degree of vertigo induced in a rotation chair, particularly when associated with nausea, vomiting, or well marked changes in the blood pressure. A healthy man responds in a certain way to rotation although the degree of vertigo varies greatly in different people, in certain persons who suffer from morbid phenomena in the air the reaction is abnormal and excessive. Dr. Henry Head has pointed out that complete adaptation to disturbances of equilibrium in the air is associated, not merely with stable labyrinths but also with automatic control of the afferent and efferent activities of lower levels of the central nervous system. A perfect pilot desires that his machine shall behave in a certain manner, and the evolution occurs, thus, however, is an acquired faculty, and may be disturbed by any condition leading to diminished control such as a gastro-intestinal attack or domestic anxiety. This loss of control over the activity of lower levels may be manifested, not only in bad management of the machine, but in some dangerous reaction, such as "giddiness" or "fainting" in the air, the former

usually associated with nausea. Careful inquiry will usually reveal the cause of this reaction, which can often be cured by appropriate treatment. Finally, though there is evidence to the effect that extremes of labyrinthine excitability are a bad sign, yet slight hyper- and hypo-excitability vary with age, training, and length of flying career, and in my opinion do not matter very much, if at all.

IV—T. JEFFERSON FAULDER, M.B., F.R.C.S., Major R.A.M.C., T.I.

ANYONE considering occupational disease from a military point of view automatically thinks of experiences, whether personal or otherwise, in the last war. That is only natural. But it would be a mistake, even in a brief survey such as this must be, to limit ourselves in that way. The reference contains the word "prevention," which greatly widens the scope not only of military but of industrial hygiene. For example, we have some knowledge of the effects of nasal obstruction in producing disease of the ears and respiratory tract. What is the influence of nasal obstruction in gas warfare? What is its influence in dusty, dangerous occupations? Taking a narrow view, I ought to begin with recruits and end with casualties. But the very facts of the last war force us to deploy, so to speak, on both flanks, and to begin with boys and end with pensioners.

In that war experiments on a large scale were going on, in preventive and curative medicine, and surgery, some of which had results likely to benefit for a long time to come not only an army but a population. It is not the fault of members of this Section if an analogous claim cannot be made for otology—as, for example, in standardizing, as it were, the effects of modern war and war conditions upon the ears, which an unwary person might expect us to be able to do.

In a former paper¹ I stated that it would not have been difficult to find an otologist who knew clinically the nasal condition of, say, a thousand fighting men. Here was a fine chance for a control test, whereby the mass of casualties might have been properly evaluated. The opportunity was missed. I cannot say that I hope it will recur very soon, but, in consequence, we have to depend upon individual experiences and opinions, and those somewhat limited. As another consequence records and statistics have to be taken with more or less reserve.

It will be profitable to make a few statements demonstrating the importance of this matter and the magnitude of the problem. I am greatly indebted to Sir Duncan Rhynod and Dr. Fitzgerald and their assistants at the Ministry of Pensions for the information now given.

The total number of first awards for various nasal disability has been 31,750. In June, 1922, there were still in receipt of compensation 23,889, and in December, 1924, there were 18,500. As a matter of interest, approximately one-half of this last total are assessed at 20 per cent or less disablement. The cost of all this disablement in a financial sense is evidently considerable.

The figures just given have their counterpart, or origin, or whatever it may be called, in the records of the men's medical histories during the war, worked out scientifically and elaborately by the Ministry of Pensions. These records show that admissions to hospital on account of diseases of the ear amount to a total of 182,440, diseases of nose 37,520, diseases of respiratory organs other than tuberculosis 801,840, tonsillitis and sore throat 441,040. It is easier to imagine than to describe the loss of man-power indicated.

How much of this mass of disease is directly due to service conditions there is no sure way of determining, we can, however, show that in the civil population there is, or was, an equally vast amount of our special diseases. I will, for convenience, leave this point till later, when I shall have something to say on recurring.

Having worked back from pensioner to casualty, we are brought naturally to field service. Time will only permit me to mention a few points.

1. Ruptured Drumhead

The most obvious and spectacular is perhaps the question of ruptured drumhead, about which various views have been

expressed, usually, in my opinion, in the direction of over-estimation. We know that granulations in the middle ear or an exposed tympanic mucous membrane can bleed spontaneously. This occurs the more readily in persons exposed to unusual stimulation as by gunfire, by jolting of wagons, and so on. Therefore blood in the meatus is not necessarily a sign of traumatic rupture. In three years I could vouch for three cases of ruptured drumhead—I mean in men who survived. In twenty years I know of no case of drumhead ruptured by the firing of a gun, except when a man by inadvertence got into the danger zone. A minor point to mention is that the membrane is not necessarily forced inward, as is commonly supposed. One of my patients had the membrane torn outwards into the meatus.

I entirely endorse all that has been said about treatment in these cases—as, for example, in the *Medical History of the War*. The ear should be cleared as far as possible of any debris, etc., without swinging, the auricle and meatus treated with iodine, and a light dressing applied. Morphine helps to relieve the vertigo, nausea, and tinnitus which are usually in evidence at the beginning.

2. The Hearing

This is a most difficult subject. We have no standards whereby to differentiate deafness due purely to war conditions from that due to natural causes. This difficulty exists even in the case of apparently normal ears. It is still greater in cases where there is already some nasal defect. There is great individual variation in powers of resistance. That was abundantly shown during the war, precisely as it is in noisy factories. One man gets impaired hearing while another under exactly similar conditions remains normal.

In a book on occupational diseases of the throat, nose, and ear by Rophe, kindly lent to me by Sir Thomas Legge of the Home Office, it is stated that in the German pre-war army deafness of a purely temporary character was common amongst the short-service rank and file, but that deafness of a more permanent sort was frequent in the long service staff of officers and non-commissioned officers. That is a kind of testimony to the theory of cumulative stimulus. I have, however, found little or no support for it in our own Royal Regiment of Artillery except as regards the temporary character of the deafness. Like others, I have observed the development of many cases of impaired hearing. They were for the most part not severe. Usually air conduction and bone conduction were both diminished, sometimes air conduction and bone conduction were apparently increased, I suppose from a form of hyperaesthesia. Some cases, notwithstanding continuance of excessive stimulation, became normal, as though resistance were developing. This, I believe, happens also in noisy factories. Other cases slowly deteriorated, but in my experience most of these begin to recover as soon as the cause was removed. This view is supported to a large extent by experiences at the Ministry of Pensions. I think it requires very prolonged or very excessive overstimulation to produce permanent deafness. There is also, as above indicated, a personal equation. On the other hand, I have seen ex-soldiers with apparently far higher degrees of deafness than are ever seen in civil practice. Some of these are no doubt due to what I might call psychological inequities. Others of them seem to be inexplicable unless we postulate permanent rupture of synapses in the cerebral tract of the eighth nerve.

3. Chronic Catarrhal Otitis Media and Chronic Suppurative Otitis Media

There is no doubt that far more disablement and loss of power is caused by disease than by injury of the ear. Chronic otitis of various kinds is also given as one of the common causes of short service. Unlike pure injury, these diseases are more or less preventable, and it is in this direction that improvement is to be looked for. Yet I erred to the conclusion that men with old perforations or eardrums of the membrane were less affected by noise and vibration than those with normal ears.

4. Preventive Measures

A number of protective appliances are made for the purpose of excluding noise and other vibrations. These are the Malloch Armstrong plug of vulcanite made with

a diaphragm, the Ward Cousins hollow rubber plug, plasticine wool, and the Macnoughton-Jones celluloid or rubber one. Incidentally celluloid is dangerous. Personally I used only plugs of ordinary wool with vaseline. All of these means protect the ear to some extent, but I do not think them necessary except in special circumstances, as when guns are being worked in an enclosed space. In proportion as they interfere with the hearing, they are disliked by most men, who prefer to be able to hear what the enemy is doing. Also I have seen orders misunderstood in this way.

5 Gas Warfare

From the medical history cards it appears that there were 440,000 admissions on account of gas. As regards pensions, in June, 1922, I find that there were on the books of the Ministry of Pensions 12,322 men disabled by gas, while in June, 1924, the number was 3,567. Some of these men have simple chronic laryngitis. Why is it that so many have recovered to an extent which justifies the discontinuance of pension? It has doubtless been noticed that nearly all persistent cases of laryngitis have some form of nasal obstruction. Now nasal obstruction *per se* is not a disability in gas warfare, because with some forms of protection it has to be produced mechanically. The inference is that primary laryngitis or pharyngitis set up by a gas irritant is prevented from recovery by nasal obstruction. Very likely this opinion applies to the rest of the respiratory tract also.

I lend with some remarks on recruiting. It is, I suppose, now a matter of common knowledge that the process of recruiting discloses a formidable amount of physical defect and ill health. One valuable source of information is the report of the Ministry of National Service. From November, 1917, to November, 1918, the medical boards dealt with nearly two and a half million examinations. Out of these no fewer than 250,280 were placed in Grade IV—that is, considered useless for any sort of service. What proportion of these were rejected on account of ear disease is hard to estimate, because the percentage rejected for that reason varies much in the different recruiting areas, in some it is about 2 per cent, in others nearly 10 per cent. Dr. Fitzgerald has explained to me that when a formal examination of ear, nose, and throat was carried out, as was done in his area of Liverpool, the result was a percentage much higher than the average, 10 per cent means nearly two divisions of troops.

On the advice of Dr. Fitzgerald I wish to amplify this statement. Grade III were men who presented marked physical disabilities or such evidence of past diseases that they were not considered fit to undergo the degree of physical exertion required for Grade I and Grade II men. 756,859 men were placed in Grade III—that is, 31 per cent, Grade IV were men totally and permanently unfit for any form of military service, 250,280 men were placed in Grade IV, or 10 per cent. Grade III and Grade IV therefore accounted for 1,007,139 (41 per cent). These men were unfit for the fighting line and for strenuous manual labour. Suppose that 4 per cent of these were ear, throat, and nose cases, and we have 40,285 men placed in Grades III and IV.

Another source of information on this subject are the Blue Books called *Health of the Army*, in which much the same tale is told.

In conclusion it appears that for any marked improvement in the incidence of ear disease in soldiers as well as ordinary people we must go further back again—namely, behind the recruit. I am informed that since the institution of medical inspection of schools there has been a great reduction of otitis media in children at the age for leaving school, some say by as much as 50 per cent. At the same time we are told that otitis media in children entering school is about as prevalent as ever. To this there are three corollaries: (1) If school inspection is worth the trouble and expense involved, it is also worth following up by action. (2) We can ask whether anything more can be done in the pre-school age. (3) We have a further argument for using the services of otologists in every fever hospital.

I have been able to touch only a mere fringe of the subject, which is important for tropical as well as for temperate climates. The ordinary life of a soldier is in general a healthy one. Service injuries and diseases of the ear are not amenable to preventive medicine, in any ordinary sense of the term. Prevention must begin at an earlier period.

Journal of Laryngology June 1911.

V-T RITCHIE RODGER, M.D., F.R.C.S.,
Honorary Surgeon Ear, Nose, and Throat Department,
Hull Royal Infirmary.

I SHALL confine my remarks to that portion of the paper which deals with the deafness induced in those who work in noisy surroundings. Just before the war, on the suggestion of Drs. Logan Turner and J. S. Fraser, with whom I was working at the time, I undertook an investigation of this subject. My conclusions for the most part were in accord with Mr. Westmacott's. His copies Barr and Habermann, however, in speaking of the high-pitched sounds prevailing in boiler shops. It is quite true that these sounds are high as compared with the rumble and whirr of the cotton mills, as Mr. Westmacott says, but they are still very low in the scale. I went down to the boiler shops in Leith with my pockets bulging with tuning-forks, and found that the predominant noises ranged round about 400 and 500 double vibrations a second. Barr and Habermann had been struck with the well marked loss of hearing for high notes, and sought to explain it by exposure to sounds of high pitch. As a matter of fact that depreciation of hearing for notes at the top of the scale is a late manifestation, and was doubtless more apparent in the cases reported upon by these observers because they were dealing with actual patients—workmen who applied for advice because their deafness was becoming a real disability. For my investigation I persuaded the workmen to come to me at the adjacent hospital, selecting men of all ages, they came not for advice but to oblige me, and several of the younger men protested that they were not deaf at all.

For the examination I used four tuning-forks—32 double vibrations to test the hearing for low notes, 419 and 512 as representing the lower and upper limits of the boiler-shop noises, and 2,048 as a fairly high note. The cases were divided into three categories—those employed less than ten years at the work, those over ten but less than thirty, and those over thirty years. In the first category every one, even the youngsters who protested they were not deaf at all, showed depreciation for forks 419 and 512, while a fair proportion had no loss at all for low and high notes, and in the others it was only slight, and among these last the high notes were actually better heard than the low. It was only in the third category—that is, the men employed over thirty years—that one met with the typical case described by Barr and Habermann with the loss of hearing for high notes a really well marked feature. This was confirmed by using the monochord for testing the upper tone limit. In the first category this was scarcely affected at all. For instance one youth could actually hear 20,000 double vibrations although his appreciation for the medium forks was reduced to two thirds. Even in the third category 60 per cent could appreciate between 9,000 and 11,000 double vibrations. These clinical results were quite in accord with the findings of the experimental work done on the Continent about the same time by Wittmann, von Eichen, Hoessle and Yoshii. Guinea pigs were subjected to loud noises for varying periods and then killed for examination of the petrous bone. The lesion in the cochlea was easily demonstrable, and the site of the trauma varied according to the pitch of the sound used. I cannot take time to detail these experiments here, but anyone interested will find a summary in my papers in the *Journal of Laryngology* (April 1915 and February, 1923), the latter paper being in argument in favour of the Helmholtz theory of sound perception based on the same investigations. Then Mr. Westmacott says of vertigo in these cases that it is only present in direct proportion to the loss of perception of the upper tone limit. That may

be so, Barr found a history of giddiness in 14 per cent of his cases and Habermann in 16 per cent. The fact that I found it in only 10 per cent may quite well be attributed to my inclusion of such a large proportion of young men in whom the upper tone limit was scarcely if at all affected.

But it must not be assumed from the juxtaposition in the opener's sentence quoted that the lowering of the upper tone limit has anything to do with the incidence of vertigo. The latter must be due to coincident injury to the vestibular apparatus. The experimental work referred to revealed no *post-mortem* change in the end-organs of equilibrium until Yoshii tried detonation instead of electric bells, when he obtained immediate clinical results, the animal showing nystagmus, rhythmic movements, and inco-ordination, as well as *post-mortem* signs of injury. When one thinks of how much the noise resembles that of repeated detonation, "holder-on" is inside the boiler with riveters hammering on the outside, one can understand the frequent incidence of vertigo.

Lastly, I agree with the opener that the mass of evidence is in favour of the view that the injury to the cochlea is conveyed by conduction, not by bone conduction. Middle-ear defects have no part in the causation. Indeed, the very opposite is the case, any middle ear defect at all, by diminishing the impact of the stapes against the oval window, will prevent the onset of inner-ear deafness. This was exemplified in 6 of the 86 ears I examined. In these either otitis media or a large perforation was present, and the signs of nerve deafness were absent. In 3 others, however, in which there was a history of otitis media of short duration, and in 2 with small perforations, nerve deafness had supervened, doubtless because the sound-transmitting apparatus was practically unaffected. Von Eicken and Hoessle in their experiments also found that the induction of middle ear suppuration or the removal of the incus prevented the onset of changes in the cochlea in the ear affected. This point, of course, is all-important as regards prevention. Wittmack's advocacy of a rubber mat was based on the idea that the injury was conveyed through the bone. Mental plugs of wax or vaselined wool was the only hope, and if workmen could be persuaded to use these regularly there is no doubt that boiler-maker's deafness would be much less prevalent.

GENERAL DISCUSSION

Mr E. B. WAGGETT confined his remarks to the subject of chronic otitis media in the army, and excluded the chronic sequelae of the influenza epidemic of 1918, of which he had no special knowledge. The subject, he said, must be considered from two distinct points of view: (1) as occurring in a nation in arms for the purpose of a war, (2) as affecting the regular standing army.

I have considered that the statistics of the great war gave a wholly misleading impression, and he believed that the very heavy figures concerning hospital entries for chronic otitis media and aural, nasal, and throat operations were to be explained on psychological rather than surgical grounds. Chronic otitis media formed a convenient excuse for the soldier desiring a holiday at the base, moreover, many men who had neglected a mild otitis media in civil life very naturally seized the opportunities for treatment afforded by the Army Medical Service. Very few medical officers had any thorough knowledge of aural diseases, and, being unable to distinguish the different causes of chronicity in otitis media—namely, infection from the meatus, the nasopharynx, and the mastoid cavities respectively—they very properly relied upon the impressive warning of the "slumbering volcano," and sent cases down to the base indiscriminately. At the base such cases must frequently have come under the charge of medical officers influenced by a desire to improve their operative technique. The speaker based these beliefs upon his personal experience of four years' field ambulance service in the front line. Thanks to the co-operation of his brother officers in the division, and of intelligent and cleanly medical orderlies, he had found it necessary to send to the base precisely one case of otitis media during the whole period of the war. He considered that the status of a chronic otitis media was,

under the conditions at the front as he had witnessed them, safer than in normal unorganized civil life. Acute cases had without exception cleared up in the field ambulance. Otolaryngology had now become a compulsory subject for medical qualification. If teachers would concentrate upon the public aspects of the subject, the next great war would be served by medical officers capable of furnishing statistical figures of a totally different magnitude.

2. The regular standing army presented a different problem, which must take account (a) of the definite fact that, for cogent reasons, the Army Medical Department could not supply competent specialists in sufficient numbers, (b) that a regular soldier must at all times be fit for field service in any war area, (c) financial considerations arising out of discharge during the six months following enlistment, etc., (d) deafness, increasing to the degree of disability, during prolonged service. For these reasons the problem had to be met and dealt with at the time of recruitment. The War Office had employed him to make recommendations on this point. He understood that these had, in the main, been accepted by the medical recruiting authorities, and if embodied in full in the new recruiting regulations they would, he was confident, satisfy aural surgeons. These regulations were not yet issued, and it was possible that the Adjutant-General's office might have found it necessary, on military grounds, to amend his recommendations.

Dr J. KERR LOYD (Glasgow) said that he would draw a distinction between true middle-ear disease in which the hearing was sometimes better in a noise, and boiler-maker's deafness, an internal ear condition in which the hearing was not better in a noise. As an example of the former, a friend of his, sitting along with her husband in the back seat of a motor car, heard what was going on in the front seat better than her husband, who had perfect hearing. The speaker asked Mr Westmacott whether he had seen what he (the speaker) had called the blue membrane of miners, a condition he had described twenty years ago, and which was due to the pressing up by the Instichum tube of cond dust which was deposited on the lining of the middle ear.

Dr T. B. JONSON (Guildford) said that in 1915 he had the opportunity of making some observations on the effect of prolonged gunfire on the healthy ear. He examined fifty German soldiers who had recently been exposed to gunfire. Cases with any history of previous ear disease, abnormal membranes, and naso-pharyngeal disease were excluded. He found that about 80 per cent of these men showed a slight diminution of acuity of hearing both for bone conduction and for aerial conduction. Examination of these cases after an interval of three to six months showed that the hearing had in almost all cases returned to normal. This corroborated Mr Faulder's remarks on the powers of resistance to gunfire of the normal healthy ear. The number of cases of serious ear injury, exclusive of wounds, due to gunfire which came under observation was small—unexpectedly small.

DIAGNOSTIC EXPLORATION OF THE NASAL SINUSES BY THE AUTHOR'S SUCTION SYRINGE METHOD

DEMONSTRATION AT THE BATH EAR, NOSE, AND THROAT HOSPITAL

BY

PATRICK WATSON-WILLIAMS, M.D. LOND.,
Consulting Surgeon for Ear, Nose and Throat Diseases, Bristol
Royal Infirmary

BEFORE proceeding to demonstrate the technique on cases requiring investigation, I would point out that the bacteriological investigation of the nasal accessory sinuses affords valuable guidance both for accurate diagnosis and for treatment. Where the discharge of pus is copious the value of the method lies in the means afforded for rapidly determining which sinuses are healthy and which involved. But few conditions illustrate the value of the suction syringe method more than those cases without purulent discharge—for example, patients in whom signs of cranial optic neuritis point to the sphenoidal sinuses or a posterior ethmoidal cell as being the probable source of infection,

though even careful anterior and posterior rhinoscopy fails to demonstrate escaping discharge, in other words, cases in which the nasal findings by ordinary methods are negative and yet the progressive optic nerve lesion renders accuracy of diagnosis of a source of infection of grave import. Equally does this apply to cases of rhinitis in which a nasal source of infection is suspected.

It is, however, in determining and exactly localizing the focus of infection when present in the sphenoidal sinuses or posterior ethmoidal cells that the suction syringe has proved most helpful. Investigations in the *post-mortem* room which I carried out in 1896 with the co-operation of Mr S. V. Stock led me to introduce a method of puncturing the anterior wall of the sphenoidal sinus and sucking any contained discharge back into the attached sterile syringe, instead of syringing out the sinus by the natural opening. Subsequently I applied the same method to the posterior ethmoidal cells, and thus with the suction syringe one can determine the presence or absence of active infective processes in either the maxillary antrum, sphenoidal sinuses, and anterior or posterior ethmoidal cells on either side.

Let us take, for example, a patient threatened with loss of vision from cranial neuritis, suspected as nasal in origin. Having explored various sinuses and found them sterile, it is necessary to make certain that no infected sinus has been "missed," because the failure to locate exactly the infected focus may cost the patient his eyesight, if nothing worse. Further, if some of the sinuses have been proved to be infected, it does not follow that they are the chief or sole source, or even the source at all, of a cranial neuritis, unless one can be certain that the other sinuses, which might cause the neuritis, have also been explored and proved sterile. Briefly, the method employed consists in attaching to a syringe a cannula suitable for entering the suspected sinus and sucking up the discharge, which is then placed in a sterile bottle and submitted to bacteriological investigation. It is usually helpful to inject a small quantity of sterile water from the syringe into the particular sinus and then suck it back with the contained discharge. By such means the bacteriology of the maxillary antra, the ethmoidal cells, and the sphenoidal sinuses can be determined individually. By centrifugalizing and making stained films of the fluids thus obtained the presence of polymorphonuclear leucocytes and often of phagocytosis, as well as the organisms present, may be noted prior to culture of the organisms by usual methods. While similar methods are often applicable to the frontal sinuses, the resort to shuntograms seems to afford all the information desired in these cavities. It is the systematic exploration of doubtful cases that has proved so helpful to the author, because by exploring both antra, the ethmoids, and the sphenoidal sinuses, it so frequently happens that those believed to be infected have proved normal while those sinuses which were not suspected have often yielded undoubted proof of infected and purulent discharge.

Diagnostic exploration by the suction syringe can be performed under local anaesthesia by cocaine, tutocain, or eucaine, etc., in all but children or highly nervous adults for whom a light general anaesthetic is desirable. With the patient then lying flat on the back, a cotton wool carrier dipped in 10 to 12 per cent solution of cocaine hydrochloride, or of tutocain or any efficient local surface anaesthetic, is carried well up and back into the middle or superior meatus, according to the route chosen and in the space of three or four minutes the patient is ready for the exploratory procedure.

For the maxillary antrum a stout curved hollow needle is used, with a bore of 2 mm., so that even thick sticky pus can be drawn up into the syringe. While it may be entered through the inferior meatal wall, it can be passed with greater ease through the middle meatal wall in the region corresponding to the processus uncinatus and with no pain (as it traverses only very thin bone or often only mucous membrane), and this is the route always chosen by the author. For the sphenoidal sinus a straight blunt trocar and cannula, measuring $4\frac{1}{2}$ inches in length, is used, and the same is used for posterior ethmoidal cells. With the patient supine, the blunt trocar and cannula are made to enter the sphenoidal sinus through the thin

anterior wall—that is, through the sphenoidal turbinate bone, avoiding, if possible, entering through the natural ostium, because it is then difficult to suck out the contents of the sinus.

For the posterior ethmoidal cell exploration the sphenoidal trocar and cannula are most readily entered through the middle meatus. The trocar and cannula are passed into the top of the middle meatus, between the ethmoidal bulla and the middle turbinal (or sometimes through the bulla), and slipped upwards and backwards until the point rests high up on the posterior oblique attachment of the middle turbinal. Just before puncturing the cell wall the direction of the trocar and cannula is rendered less oblique by raising the instrument, and, if necessary, the tip or the nose, and it is now made to take a slightly outward direction. The instrument is then gently pressed through the thin anterior wall of the posterior ethmoidal cell or cells, so as to enter the posterior cell just outside the thicker bone which corresponds with the attachment of the middle turbinate bone. Care should be taken not to fracture the outer wall (into the back of the orbit), nor to direct the point too much upwards through the roof into the cranium. If this route is followed, and the pressure made somewhat outwards and but slightly upwards, there should be no risk of accident in skilled hands. When the point has fully entered the cell, the cannula is held steadily *in situ*, while the trocar is withdrawn and the suction syringe, containing about 3 c.c. of sterile distilled water, is attached as in exploring the sphenoidal sinus.

A slight movement of the piston to and fro serves to wash the water into the sinus and suck it back—it may not go quite so easily as with the sphenoidal sinus, probably from a difference in the size of the cell's natural ostium, which serves as a bung-hole. As it is essential to use a sterile instrument and sterile syringe for each sinus explored, the author has six syringes, four sphenoidal trocars and cannulas, and two anti-curved needles at hand so as to avoid unnecessary delay in sterilizing any of the used instruments during the course of exploration. The whole procedure, apart from cocainization, usually occupies two minutes only, and often less in cases under general anaesthesia.

Having thus entered a sinus cavity, the blunt trocar is withdrawn and the syringe attached to the proximal or piercing end, and the sample of the investigated sinus content sucked into the syringe. If much pus is lying in the sinus, it may appear in the syringe in ropes, or as very bloody mucus, leaving one in no doubt as to the sinus being infected. In other cases the fluid extracted may be perfectly clear and watery, proving sterile on culture. Other samples obtained may be suspicious only, and doubtful until submitted to film and culture examinations, which may either prove negative or definite phagocytosis, abundance of polymorphonuclears and pyogenic cocci may afford conclusive evidence of active infection.

The posterior ethmoidal cells are similarly explored by the blunt trocar and cannula entered either above and internal to the middle turbinated body, or, as I usually find much simpler, by piercing the posterior ethmoidal cell wall beneath the attachment of the middle turbinated body to the outer wall of the nasal passage.

With the maxillary antrum, ethmoidal cells, and sphenoidal sinuses explored thus through the right and left nasal passages, at least six samples have been obtained for investigation by the pathologist, which, if the anatomical arrangement of the sinuses be normal, should yield exact and reliable information as to the normal or infected condition of each sinus. Unfortunately, the sphenoidal sinuses and ethmoidal cells are often most irregularly developed. For instance, one sphenoidal sinus may be very large and extend right across the midline, pushing the sinus of the other side which is correspondingly small, so far outwards that the exploring cannulas passed backwards through the right and left nasal passages enter the one large sinus, the other small one being altogether missed. This is not difficult to discover if, with both cannulas in one sphenoidal sinus, water injected down one will come back through the proximal end of the other. If left in doubt as to whether one has entered the sphenoidal sinus instead of the ethmoidal cell, by again keeping both cannulas *in situ* and injecting

water down one it is quite easy to determine whether the two canals be in the same or in separate cavities. Such piercations are by no means fanciful, and I have met with cases of encephalic optic neuritis where the sinus infection did not correspond with the retinal defects until further careful exploration revealed such irregularities as I have described, and which had very nearly led to the source of the very serious ocular defect being missed and the patient unrelieved.

A NEW METHOD OF FITTING ARTIFICIAL LEG SOCKETS

BY

E. MUIRHEAD LITTLE, F.R.C.S.,

CONSULTING SURGEON, ROYAL NATIONAL ORTHOPAEDIC HOSPITAL

ONE of the greatest difficulties in fitting an artificial limb after amputations in general, and particularly after amputations of the thigh, has lain in the method of attachment of the false limb to the living stump. The ideal must be so to connect these two that the prosthesis shall partake of all movements of the stump in all directions as though it were part of it. Any movement, whether longitudinal or angular, which occurs between the socket of the artificial limb and the stump—what is called by mechanicians "lost motion"—is a source of weakness, gives rise to troubles in the skin of the stump, and is to be eliminated as far as possible.

In the case of amputation of the thigh the attachment has hitherto been made by means of straps or suspenders passing over the shoulders, and by means of belts around the pelvis made of steel, leather, or woven fabrics. When the patient with such an attachment assumes the erect position and rests some or all of his weight upon the limb, the pressure is transmitted almost entirely through the ischium, which bears upon the inner upper edge of the socket. Very little weight is taken on the thigh stump itself in most cases. When, as in taking a step in ordinary walking, the weight is transferred to the sound limb and the artificial limb is swung forward, the socket slides down upon the stump to a greater or less extent, until its movement is stopped by the suspenders or pelvic band. When weight is once more put upon the artificial limb, as the sound one comes forward, the stump descends into the socket until its movement is stopped by contact between the ischium and the top of the socket. When the patient sits down a similar descent of the prosthesis occurs, so that the artificial knee is more prominent than the living one. It has been the constant aim of the limb-maker to reduce this movement to a minimum, but it is nearly always to be detected. Out of thousands of cases of amputation of the thigh which came under my notice at Roehampton and elsewhere, only one was able to dispense with all straps and belts for the attachment of his artificial leg. This was an officer who had a very long stump, and who had found out that he could so jam it into the socket that the prosthesis would not drop off of its own weight. He thrust his stump into it as one might thrust a foot into a riding boot, and walked off without any suspender or belt whatever.

Some two years ago Mr. Ernest Underwood, a pensioner who had suffered amputation through the middle of the

femur, made himself a wooden socket, not shaped *secundum artem*, but actually turned in a lathe with three or four inch-wide annular grooves on the inside fitting the bare stump as closely as possible. Wearing this he was able to give up all suspensory attachments. His stump measures 9 inches in length from the tip of the great toe to the knee. It has an end posterior scar which is partly adherent.

From past experience I should have been strongly sceptical of the possibility that there could be any practical value in such a method of fitting, but last July Messrs. Charles A. Blatchford and Sons, Ltd., who had for some time been patiently working upon Mr. Underwood's rather crude idea, brought him, and four other amputees wearing socket fitted on his principle, to see me. There was then no room for doubt that, in these cases at least, the method was a complete success. Since then I have been shown six other cases fitted with equal success, and have had opportunities of watching the progress of all the eleven cases, of which short notes are subjoined.

CASES

1 D. J. A., aged 32. Amputation, September, 1916 of right thigh 9½ in. below trochanter. Posterior scar. Seen August 27th and October 6th, 1925.

2 J. F. C., aged 42. Amputation of right arm and right thigh in 1917, 14½ in. below the trochanter (he is a very tall man). Posterior scar on which he has formerly borne weight. Seen July 27th, September 1st, and October 6th, 1925.

3 S. D., aged 30. Amputation (in Germany) August, 1918, right thigh 10½ in. Posterior scar. Seen August 27th and October 16th, 1925.

4 H. G., aged 26. Amputation October 1917, 12½ in. End scar adherent. Seen August 27th and October 6th, 1925.

5 T. G. G., aged 33. Amputation August 1916 left thigh 9½ in. Extensive posterior and internal scars. Seen August 27th and October 16th, 1925.

6 A. I. J., aged 28. Amputation February, 1918 left thigh 13½ in. Posterior scar. Seen July 27th and October 16th, 1925. This patient is a record breaker for walking in an artificial limb. He walked the mile in 11 minutes 8 seconds wearing a limb with shoulder control. In this limb he has done it in 9½ minutes, and 4 miles in 45 minutes.

7 J. I. Amputation September, 1916 right thigh, 12 in. Posterior scar. Seen August 27th and October 6th, 1925. A localized thickening of the derma, commonly called a cyst, which was caused by his former loose socket, is now disappearing.

8 T. W. P., aged 28. Right thigh 10½ in. Posterior scar not adherent. Seen July 9th, 1925 when the following note was made.

Cannot be pulled off without very great effort and when he relaxes his muscles when he opposed I could not pull it off at all. Seen again October 6th, 1925.

9 C. T., aged 42. Amputation December, 1917 right thigh 13 in. Very conical stump, muscles much retracted, scar not adherent. Seen July 30th and October 19th, 1925.

10 D. U. Right thigh, 9 in. End and posterior scar partly adherent. Wearing a socket with groove of three turns of a spiral and one ring at bottom. Seen July 18th and October 6th, 1925.

11 J. N. Left thigh, 8 in. End scar not adherent. Seen October 6th and November 2nd. This patient is only now (November 2nd) just beginning to use the leg continuously. Although he has been used to a pelvic band and hip joint, on account of his short stump, he walks better in this limb without that addition.

FIG. 1.—Diagrammatic drawing of a socket showing the groove and the valve.

The socket is made of aluminium, and experience has shown that a spiral groove of a little more than one turn is enough. The groove is 1½ in. wide and 1/8 in. deep. It is shown in the diagrammatic drawing (Fig. 1). The socket is made to fit without any sock as closely to the stump as is consistent with comfort, but the end of the stump is left free. This fit is so close that a partial vacuum is created when an attempt is made to withdraw the stump, and an rushes in with an audible noise as the socket leaves the stump. To facilitate withdrawal a spring valve is fitted on the socket, through which air may be admitted when it is desired to remove the leg. Attempts to pull

off the limb by main force without opening the valve failed in all cases. The patient might be pulled across the floor by the artificial foot, but the limb seemed to be as firmly attached to the trunk as was its living fellow. It appears to me that it is not so much the vacuum as the close contact made by the metal socket and its groove which holds the leg on. This opinion is supported by a recent experience of a case in which there was positive air pressure below the end of the stump, so that on opening the valve air rushed out with force enough to blow out a match.

FIG 2—Demonstrates the absence of angular or tilting movement between stump and socket

It might have been feared that this close contact and the absence of ventilation would have a bad effect on the skin, or that the constant pressure might cause atrophy of the upper part and oedema of the end of the

stump. In practice I have found that such fears are groundless—at any rate in the cases of the eleven men in question. After wearing these sockets for periods varying from two months to two years the skin is in a healthier condition

than before, and the stumps have increased in circumference. The absence of friction between skin and socket eliminates the risk of sores and callosities, and the increased use as a lever of the stump, which is rendered possible by its close alliance with the socket, appears to have led to increased development of muscle and better nutrition of the stump. It is a commonplace of limb-fitting that the better a limb fits the less is its weight felt. Therefore it is not surprising that the wearers of these sockets make light of their disability.

As regards the question of ventilation, it seems likely that the partial vacuum may be dispensed with, in which case the lower end of the socket might be ventilated in the usual way. As regards the close-fitting metal socket, which in the nature of things allows no ventilation of the skin, it is to be remarked that this is made of thin metal and is suspended inside the metal thigh-piece, which is itself freely perforated. There is thus an air space all round it with free circulation.

Figs 2 and 3 show how firm is the hold of the socket on the stump.

As far as I know, this method has not been tried in artificial arms, but there seems no reason to doubt that it might be adaptable to certain cases of amputation above the elbow.

FIG 3—Shows the strength of the adhesion between stump and socket. The whole of the lower man's weight is borne by the artificial limb.

INTESTINAL OBSTRUCTION DUE TO GALL STONES

In my comparatively limited experience I have seen several cases of this kind. One I operated upon in 1914. The patient was an old man, aged 78. He made a good recovery. The case is fully recorded in the *Liverpool Medico-Chirurgical Journal* of 1915. The calculus weighed 418 grains and measured 2 inches in length and $1\frac{1}{2}$ in breadth. The circumference measurements were $5\frac{1}{2}$ and 4 inches. The specimen is in the Royal College of Surgeons Museum in London.

STRICTURE OF THE VAGINA DELIVERY BY CAESAREAN SECTION

In May, 1925, Dr. Minett asked me to see a case for her at the Tsung Yuen Hospital.

The patient, aged 36, was pregnant for the second time. She came into hospital because her first labour, thirteen years earlier, had been difficult. She was delivered in a Chinese village; no instruments were used, apparently. The child was full term and was dead.

The external pelvic measurements were: interspinous 9 in., intercrural 10 in., external conjugate $7\frac{1}{2}$ in. At the time she was about eight and a half months pregnant. There was a very rigid stricture admitting only the tip of one finger, situated at the junction of the middle and lower thirds of the vagina. It appeared to have resulted from trauma during the previous confinement, but no details were available. The patient was told to return in a month for further examination.

When she next presented herself it was decided to perform Caesarean section shortly before the estimated date of full term for the following reasons: (1) Any attempt to incise or dilate the stricture would inevitably lead to extensive laceration during the delivery of the head. (2) The patient had no living children, and had not been pregnant for thirteen years, and further there was a great probability of the pelvis being contracted, although no internal measurements could be taken owing to the stricture. The child was alive and healthy.

The external measurements of Chinese women appear to be smaller than those of European women, the average of five patients who delivered themselves is as follows: Interspinous $9\frac{1}{2}$ in., intercrural $10\frac{1}{2}$ in., external conjugate $7\frac{1}{2}$ in.

I wish to thank Dr. Minett for having asked me to see, and treat, the case, and for her kindness in superintending all the arrangements for the operation.

Professor of Midwifery, University of Hong Kong.

"NEURASTHENIC" NEURALGIA

The following case is worthy of being placed on record as it demonstrates the importance of a routine x-ray examination in all cases of intractable neuralgia.

Mr. D., a well-developed man, aged 49, consulted me with regard to a 'new wisdom tooth'. He also complained of neuralgia which had attacked him frequently during the last seven years. He said that about six years previously his doctor commenced medicinal treatment for the neuralgia. As there was no improvement at the end of the month the doctor advised the removal of all his teeth, although they appeared fairly good. This drastic measure gave no relief, and finally the patient was described as neurasthenic and apparently abandoned.

Examination showed a healthy edentulous mouth except for a small mass of enamel near the middle line which I diagnosed as an unerupted supernumerary central incisor. Under a local anæsthetic the gum was reflected and a portion of the external alveolar plate removed, exposing deep in the alveolus a very large perfectly developed canine which I removed. The appearance of the periodontal membrane suggested hyperæmia, otherwise the tooth was healthy.

In reply to questions the patient stated that as far as he was aware there had been no abnormality in his dentition. Three months later he returned for new dentures and then volunteered the information that since the removal of his wisdom tooth his neuralgia had completely disappeared.

It would appear that an x-ray examination would have saved the doctor considerable trouble and the patient much suffering.

Lower Bebbington, Cheshire.

FATAL CASE OF GASTRIC TETANY

In a recent number of *Surgery, Gynecology and Obstetrics*, vol. 41, No. 5, a case of gastric tetany was reported, the pathological condition being indefinite. The following case presents the usual clinical and pathological picture, the obstruction was due to a chronic ulcer of the pylorus.

A man, aged 44, had had a history of vomiting, epigastric pain, and flatulence for twelve months. Six months previously he was said to have had an operation on the stomach, no relief of the symptoms followed, and the patient gradually became worse. He had lost 5 st in weight in the course of the last year, and during the week prior to admission he vomited all food taken. No previous account of tetany was elicited.

On examination the patient was found to be emaciated and obviously distressed. He was vomiting brownish fluid at intervals, and there was epigastric tenderness. On the next day he became collapsed after a prolonged spell of vomiting, and was delirious during the afternoon. The following day a carpopedal spasm was present, also "main d'accoucheur," clamps in legs, and twitchings of the facial muscles.

At the operation a large gastric ulcer was found on the lesser curvature, encroaching upon the pylorus, and posterior gastro-enterostomy was performed. The tetany was relieved by the operation. The patient's condition improved, and the vomiting was much diminished. Later on the vomiting returned, the patient gradually became weaker, acute dilatation of the stomach set in on the twelfth day, and death followed twelve hours later.

The necropsy showed a large chronic gastric ulcer encroaching on the pylorus and causing stenosis.

I am indebted to Dr. A. D. Nelson, medical superintendent of Wanganui Hospital, for permission to publish this case.

OPERATING TABLE RACHIALGIA

It is quite common, after abdominal operations, to hear patients complain of pain in the back, which, as often as not, we attribute to some inoperable peritoneal or intestinal reflex disturbance, but one cannot fail to be struck with the incidence of such pain following operations on gall bladder and kidney, in which, by the way, dorsal pain is a frequent symptom, this induces one to allow for some post-operative exacerbation caused by the necessary manipulation of the inflamed organ, but on close inquiry another factor arises—namely, the method whereby the Robson or renal position was required, and the duration.

There are three forms of table in common use: (1) in which the particular position is obtained by adjustment of segments of table, (2) elevation of part by rack with cross-bars, (3) an ordinary flat table on which sandbags are placed for a similar object.

I have had an extensive experience of the last mentioned, and am bound to state that it causes much less subsequent backache than the first, which I now rarely use except to procure the Trendelenburg position. I have never employed the second method, I looked on metal crossbars for such purpose as unhygienic, but I consider them essentially useful for operations on the cadaver.

This lesion is so common that I think it opportune to invite attention to its prevention, and beg of my surgeon who wishes to test the validity of the above statements to give credence in Robson position, without anaesthesia, a personal trial for ten minutes (by the watch), allowing, for obvious reasons, an interval of one month between the sciences.

It is almost unnecessary to repeat the verdict of surgeons engaged in the late war that the most important detail in prevention of operative shock is heat, and as electricity is now ubiquitous there is no person why such a particularly appropriate and ready method of elevation should not be applied to all operating tables, only a thin rubber-covered mattress is required to insulate. It makes a warm, cosy bed for the patient, who should always, in abdominal operations, have the limbs and thorax wrapped up in wool and a macintosh enveloping that, all secured in position by strong safety pins. The windows should then be opened so that patient and operator may have full advantage of fresh air. The operating theatre which does not receive its meed of sunlight is a microbe hunt.

JOHN O'CONNOR, K.B.E., M.D.

Reports of Societies.

OBSCURE PYREXIA IN CHILDHOOD

At a meeting of the Medical Society of London on November 8th, the President, Sir HENRY J. WARR, in the chair, Dr. ROBERT HUTCHINSON opened a discussion on obscure pyrexia in childhood.

Dr. Hutchinson stated that he classified the obscure pyrexias of childhood in three main groups: cases of acute fever lasting more than a week, cases of fever recurring in bouts, and cases of prolonged but slight fever continuing over a period often of years. In the first group a child was acutely ill with fever lasting for about a week or so, but without obvious physical signs, such a case was far too often labelled "influenza." Influenza, except during an epidemic, was rare in children, and if no complications occurred the fever did not last a week. In these cases of acute fever the enteric group of infections should be thought of first, the paratyphoid type seemed to be more common since the war, and in many cases in children classical signs, such as the enlarged spleen, the rash, and diarrhoea, might all be absent. Blood culture or agglutination reactions would quickly clear up the diagnosis, other diagnostic features included leucopenia and a relatively slow pulse. A frequent cause of obscure pyrexia in this group was an overlooked pneumonia—undetected because it was deep seated or at the extreme apex of the lung. Dr. Hutchinson emphasized the importance of very light percussion, and also drew attention to the increased respiration rate and to the occurrence of the "mottled" type of breathing in these cases. The next important cause of fever without physical signs was infection with the *Bacillus coli* group, especially the condition of *B. coli* pelitis. Cultural examination of the urine gave proof of this, though in the early stages the urine might appear normal to the unaided eye. A high swinging temperature with little constitutional disturbance, a reluctance to being handled, and the microscopic discovery of pus cells and bacilli in the urine, would enable a diagnosis to be made. The therapeutic test of administering alkalis was also very valuable. Cases of so-called "milder septicaemia," where the source of infection was not discoverable, were very rare in children, and signs of profound constitutional disturbance were usually to be found. Of the minor troubles which might produce an acute fever, Dr. Hutchinson mentioned acute otitis media, where the child complained of little earache and where the drum was difficult to see, teething, which was a common sort of serpegant diagnosis but which appeared to be a genuine cause of fever in two cases he had seen, and constipation. Among the rarer causes mention was made of acute leukaemia, where anaemia, the presence of enlarged glands and spleen, and a blood count soon enabled a diagnosis to be made, and lastly, acute tuberculous infection, which might cause fever long before there were any physical signs present. In this connection the importance of pyrexia, a very rapid pulse, and possibly the presence of choroidal tubercles, were mentioned. The speaker insisted on the difficulty of finally excluding tuberculosis in a case of this sort, and also on the importance of endeavouring to make a diagnosis, since the prognosis of this variety of tuberculous infection was so very bad. The second group of cases with recurrent bouts of fever were commonly due to an "alimentary" origin, called "food fever" by Estree Smith. The liver appeared to be the organ at fault, and it had been suggested that this organ accumulated imperfectly metabolized material which at intervals was suddenly utilized and burnt up, causing the pyrexia. These cases were very similar to those of cyclic vomiting, and vomiting and pyrexial attacks might alternate. Milk, eggs, and cream must be cut down, and mercury and rhubarb used as aperients. Another cause of the recurrent type was a latent source of sepsis, especially in the tonsils, where the tonsillar glands were nearly always enlarged. Chronic *Bacillus coli* infection, especially in older children and in girls, was a not uncommon cause, and the urine might be normal between the attacks. In the

colitis had again to be considered, but was not a common cause of this type of fever. The third group of prolonged slight fever, usually at night, often lasting for months and even years, was frequently due to tonsillar infection. Other causes included mucous colitis, when the faeces would indicate the diagnosis. Latent rheumatism was probably very rare, if it really existed without giving some signs or symptoms. The question of tuberculosis had again to be considered, but it was exceptional for a case of this type to develop obvious tuberculosis infection at a later date. Instability of the heat-regulating mechanism seemed to be a cause occurring occasionally after such a disease as pneumonia, but "neuro-mimetic" pyrexia never occurred in children, and even in adults Dr Hutchinson believed it was always fraudulent.

Dr WILFRED PEARSON agreed as to the importance of pyelitis and of aurial infection as commonly missed causes of fever. He referred to several of the problems in the alimentary group of cases, pointing out that insufficient fluid, ingestion of excess of sodium chloride or of certain proteins might give rise to pyrexia, but nothing appeared to be known of the mechanism of this. With regard to the persistent slight fever cases, he insisted on the fact that up to the age of 10 the normal temperature for the child in the morning was 99° and in the evening 99.5°, and slight variations due to such causes as excitement were not uncommon. Similarly certain families appeared to have a raised normal temperature. Dr Pearson discussed the difficulty of diagnosing tuberculosis in which a steady loss of weight was very frequent, from "mucous" disease and chronic infection of the nose or throat.

Professor LANGEHEIM agreed as to the frequency with which *Bacillus coli* infections were missed, but he thought the constitutional disturbance more serious than indicated by Dr Hutchinson. Otitis media was a real danger, and might even be overlooked when the drum was well seen. He agreed that teething might be a cause, as also roundworms. The alimentary group comprised constipation, colitis, cyclical vomiting without any vomiting, and certain food idiosyncrasies. He thought latent rheumatism did exist and accounted for a certain number of cases of mitral stenosis in later life. Latent tuberculosis appeared also to be a cause of many fevers, but fortunately this latent type was a benign disease. Easily diagnosed, obvious tuberculosis was usually fatal in young children.

Dr WALTER BROADBENT referred to certain cases of streptococcal sore throat in children, due, he thought, to the presence of manhole ventilators near the children's homes. He also confirmed Dr Hutchinson's views as to teething as a possible cause, and recommended fanning of the gums as a more frequent practice.

Mr CECIL ROWTHREE described the frequent occurrence of enlarged mesenteric glands indicating in old tuberculous infection, and suggested that in x-ray of the abdomen, by showing early flocculent shadows, might help the diagnosis of some obscure fevers.

Dr G. D. S. WARD described a case diagnosed as enteric fever with enlarged spleen, prolonged pyrexia, and a "typical" tongue, all these signs disappeared after a round-worm was vomited. In a second case diagnosed as tuberculous meningitis all the symptoms, including pyrexia, disappeared after the lid of a doll's teapot was vomited.

Dr CASTELLANI described "parenteric" infection as a possible cause of these fevers, and emphasized that intestinal parasites were also not infrequently responsible for a pyrexia of obscure origin. Dr F. G. CHANDLER referred to tuberculosis of the mediastinal glands. Dr GORDON GOODHART and the PRESIDENT both mentioned the frequent occurrence of *Bacillus coli* in the urine apart from pyrexia.

Dr ROBERT HUTCHINSON briefly replied to many of the points raised. Some of the persistent slight febrile cases were best dealt with by ignoring them. He thought the connexion of bad drums and sore throats was certainly established, although a little difficult to understand, and he emphasized what Professor Langmead had said, that fortunately latent tuberculosis as a cause of obscure pyrexia had in general a good prognosis.

PRE-CANCEROUS STATES

A discussion on this subject took place at a meeting of the Section of Surgery of the Royal Society of Medicine, held on November 4th, with the President, Sir LENTHALL CHEATLE, in the chair.

The discussion was opened by Dr J. H. SEQUEIRA, whose remarks were illustrated by a very fine series of lantern slides. He dealt with the pre-cancerous conditions of the skin. These he divided into (1) congenital and (2) acquired forms, they were characterized by atrophy of the skin, pigmentation, and hyperkeratosis. With reference to the duration of such conditions the speaker recalled that Sir Frederick Tieses used to tell his students that every patient with leucoplakia of the tongue would develop cancer if only he lived long enough. The pre-cancerous conditions of the skin described and illustrated by photographs were:

1 *Tylosis*, a familial condition of hyperkeratosis, which in some members of the family became cancerous.

2 *Xeroderma pigmentosum*, a congenital and familial state of extreme sensitiveness to sunlight, in which the exposed skin showed excessive freckling, telangiectases, and warts, epithelioma might supervene even in childhood. A similar condition might occur in adults. A detailed account was given of a farm labourer in Essex, who came every summer for hospital treatment on account of the development of very numerous warts upon his face, some of these had been excised and had been found on microscopic section to be epitheliomatous. These tumours were clinically not very malignant except at mucocutaneous junctions.

3 An affection consisting of very numerous warts on the backs of the hands in persons exposed to sunlight, especially common in Australia.

4 *Sailor's cancer* (*Seemannshaut* of Umm) in sailors and other outdoor workers.

5 *X-ray dermatitis* showing pigmentation, atrophy, and hyperkeratosis. This might follow a single burn but was more often the result of many short exposures. Formerly about 2 per cent of cases of lupus became epitheliomatous, after the introduction of x-ray treatment the percentage was much increased, many such cases had received 200 to 400 exposures. Photographs were shown of a case of cancer of the wrist in a taxicab driver following x-ray treatment of lupus of the forearm, in which the situation of the growth seemed to depend upon friction against the side of the cab. A case of cancer following non-irradiated lupus was shown also.

6 Workmen exposed to tar and crude anthracene likewise showed pigmentation and atrophy of the skin, warts, and epithelioma, the men treated such warts with caustic soda.

7 *Arsenic*—The keratoses of the palms and soles were characteristic, and resembled the condition in tylosis, there was a peculiar "rindop" pigmentation. A patient whose case was described had taken arsenic for nine months in the year for thirty-five years. Epithelioma occurred also in men making arsenical sheep dip, whether the absorption of arsenic in them took place through the skin, alimentary, or respiratory tract was not clear.

Among the cases illustrated were (1) An epithelioma in a woman of 85 under a wedding ring worn for fifty years. (2) An epithelioma of the thumb in a baker, the site of the growth had come into frequent contact with a hot poker, though no actual burn had occurred. The similarity to the kangri cancer of Kashmir was pointed out. (3) Multiple basal celled carcinoma (rodent ulcer). The suggestion was made that such cases were more common than was supposed, and might be mistaken for psoriasis. (4) Cancer of the tongue in a shoemaker at the point of contact with tools which the man held between his lips, there was syphilitic glossitis.

Sir LENTHALL CHEATLE referred to two terms (1) *desquamitate*, and (2) *dysgenetic epithelial hyperplasia*, the latter included the malignant conditions. A large series of sections of tumours of the breast illustrating these states was shown. When a malignant growth was produced by application of tar to the skin of a mouse, or man, four successive stages could be distinguished (1) *desquamative hypertrophy* with lymphocytic infiltration of dermis, (2) a *wart*, (3) growth downward, but not beyond normal limits, (4) invasion of deeper tissues. Now Dr J. A. Murray had shown that if cells from Stage 3 be transplanted to another part of the same animal they continued to grow and formed metastases—that was to say, they were malignant—whereas cells transplanted similarly from Stage 2 either atrophied or formed non-malignant cysts.

Hence cells in Stage 3 were potentially malignant, although not yet invading other tissues. The same four stages could be distinguished in tumours of the breast, the first two of them were to be classed as pre-malignant.

Mr SAMPSON HANDLEY was not in favour of a distinction between pre-malignant and pre-cancerous states, since both might precede cancer. He emphasized the importance of changes in the connective tissue. Epithelium was nourished from connective tissue, and hence might be said to be an obligatory parasite upon it. The normal desquamation of the skin illustrated the death of epithelium when removed sufficiently from connective tissue. Carcinoma followed long-continued changes in the connective tissue. Victor Bonney had demonstrated accumulation of lymphocytes and plasma cells in the dermis in pre-cancerous conditions. A section was shown of gastric carcinoma cells attaching themselves to the peritoneal connective tissue in the region of the umbilicus. Cancer nodules in lymphatics, when of sufficient size showed central necrosis. Around a lupus nodule there was lymphangitis, leading to a blocking of lymphatics, probably thus caused an auto-intoxication which was of importance in the production of cancer. Deviation of the nipple in chronic mastitis was an important sign of malignant change. Mr Handley described a case of cyst adenoma of the breast in which an innocent tumour formed a large protruding fungating mass.

Mr ZACHARY COPE dealt with the pre-cancerous conditions of the alimentary tract, which he classified as follows:

1 *Of the mouth* (a) Leucoplakia. He described a case of cancer in a leucoplakial tongue, which he removed. There was no recurrence, but later a second cancer appeared in a patch of leucoplakia upon the gum. (b) Any papilloma of tongue or cheek. (c) Dental ulcer.

2 *Of the stomach*. The relation between gastric ulcer and gastric cancer had been a subject of controversy since 1840. In 1900 Osler and McCrue collected 150 cases of gastric cancer, in only 4 of them was there any history of gastric ulcer. Some later American authors found a history of gastric ulcer in 71 per cent of cases of gastric cancer, but in a later paper by them this percentage was reduced to 7.9. One hundred cases of gastric cancer analysed recently by the Manchester Cancer Committee gave very little evidence of association with ulcer. The speaker's own impression was that the percentage in question was nearer 5 than 70. If every case of gastric ulcer which perforated—in which there was therefore no doubt that ulceration had occurred—were followed up for five years, there would soon be decisive evidence on this question.

3 *Of the small intestine* papilloma.

4 *Of the colon*. Many cases of multiple papilloma were pre-cancerous. There was no evidence that dysenteric ulceration, or diverticulitis, led to cancer. He did not consider that there was enough evidence upon the alleged relation of intestinal stasis to cancer, although one could not deny that any toxæmia might possibly be of importance in this respect.

In the course of the discussion which followed, Dr SNAY described various forms of chronic inflammation, and made a plea for the establishment of a national pathological museum. Dr H. W. LIVINGSTONE compared the chemical state of acutely and chronically inflamed tissues and said that the latter resembled Dr Gye's culture medium. Mr J. E. ADAMS referred to 135 cases of chronic mastitis, in only 4 of which cancer of the breast was known to have developed. Mr LOCKHART-MUMMERY considered that papilloma were the preceding condition in 80 to 90 per cent of cases of cancer of the large intestine, and were the source of the multiple cancers, sometimes three in number, of this part of the intestine. He had known an adenocarcinoma of the colon to occur in a patient eighteen years after excision of the rectum for cancer. He agreed with Mr Zachary Cope that ulceration of the colon was not a precursor of cancer.

ANAESTHETICS IN CHILDREN

At a meeting of the Anaesthetics Section of the Royal Society of Medicine held on November 6th, with the President Dr F. E. SHIPWAY, in the chair, Dr HAROLD SINGTON (London) read a paper on anaesthetics in children.

Dr Sington began by saying that it could not be sufficiently emphasized that a child was not a diminutive adult. The central nervous system of the child was much less stable than that of the adult, and was receptive of impressions which might persist throughout later life. It was

necessary, therefore, to endeavour to gain the patient's confidence beforehand, and to take great pains during induction to avoid as far as possible unpleasant impressions and to shorten the period of induction to a minimum. Preparatory to operation, atropine sulphate should be given by the mouth, and not hypodermically. The dosage employed at the Great Ormond Street Hospital was: Up to 6 months 1/300 grain, from 6 to 12 months 1/200 grain, from 1 to 2 years 1/150 grain, and from 3 to 6 years 1/75 grain, in solution in drachm doses, given one hour before operation. Over 6 years two doses of 1/100 grain were given two hours and one hour before operation respectively. Purging and enemata were dispensed with, starvation avoided, and glucose administered for several hours beforehand. Each case had to be treated on its merits, but there should never be any hurry in the matter of induction, and the child should never be deceived. Attempts should be made to explain things to the child, but once he had started to breathe the anaesthetic the induction period should be shortened as much as possible compatible with safety. Ethyl chloride and ether was the anaesthetic of choice in nearly every case, and was perfectly safe if there was a free airway. In dental cases ethyl chloride was the ideal anaesthetic for children. In 10,000 cases he had met with no fatalities, and only in 2 cases had there been cessation of breathing, both patients showed evidence of asphyxia, but recovered and were able to go home two hours later. When ether followed ethyl chloride his procedure was to give essence of orange in alcohol as a preliminary to spraying on the ethyl chloride, 3 to 5 c.c.m. In about three breaths the child was unconscious, and ether could be given in rapidly increasing doses. Ether was so far the best anaesthetic for children, and the only exceptions to this rule were when the actual cautery was to be used and in certain special cases mentioned later. Induction by chloroform and mixtures containing it was dangerous. Gas and oxygen with a minimum of ether vapour was the anaesthetic of choice for operations for congenital hypertrophic pyloric obstruction, acute intussusception, and in cases where there was prior starvation and much shock. Lastly, Dr Sington pointed out certain helps to the comfort of the child—for example, in the case of the dissection of tonsils. Anaesthesia should be deep, for then the tissues became lax, haemorrhage was slight and easily controlled. The throat should be kept free of blood, and there must be complete co-operation between the anaesthetist and the surgeon. The mouth should be swabbed out with normal saline solution at the end of the operation to avoid any blood sticking to the tongue. Recovery was made quicker if sedatives such as potassium bromide gr. xx and aspidium gr. x were given per rectum when the patient got back to bed.

Dr JOSEPH BIRT (London) said that he had given gas and oxygen in some 250 cases, including many of pyloric stenosis. There was little shock if cyanosis was avoided. Great vigilance on the part of the anaesthetist was necessary for the nice adjustment of the percentage of oxygen given. Breath holding, which occurred at times, could be combated by rubbing the abdomen and giving more oxygen reinforced with a small amount of ether. The ether vapour should be obtained by passing the gas over, and not through, the ether. The gas should be made to emerge close to the mouth, and not at the far end of the bag. The ether was necessary, especially at the initial incision, when closing the peritoneum, and at the final suturing of the skin. A narcotic should be given at the end of the operation. As some free pieces did not fit well, he had found it useful to insert a wet pad of Gamgee tissue under the mask.

Mr THURSTON HICKINS (London), speaking as a surgeon, said that experience was very necessary in the anaesthesia of children, and there must be understanding between surgeon and anaesthetist. He agreed with all that Dr Sington had said. The abolition of chloroform as an anaesthetic for children was a distinct advance. Ether was the anaesthetic of choice, with gas and oxygen as an adjunct in the type of cases mentioned. He asked whether there were any lines on which improvements could be made to interpose further buffers against psychic shock. A non-toxic anaesthetic was needed, and improved methods

of administration in certain cases. Several operations could be made more comfortable, such as those on the brain, neck, mouth, larynx, chest (especially for empyema), and he asked whether the solution could not be found in the employment of rectal anaesthesia.

Mr A. T. PIRTS (London), a dental surgeon, said that he found ethyl chloride the best anaesthetic, as it produced a quiet, deep anaesthesia lasting from two to three minutes, enabling the surgeon to remove milk teeth leisurely and carefully, which called for more skill and care than was usually thought necessary. Gas did not afford the surgeon time to extract with care, and often necessitated second visits to the surgery—visits which were unpleasant to the child and an expense to the parent, not to mention a disturbance in the domestic arrangements of the mother in the poorer class patients. The second visit, consequently, was often avoided, with possible ill effects from caries on the permanent dentition. In country districts where skilled anaesthetists were rare he thought it better that ether should be given rather than indifferently administered gas or ethyl chloride.

The PRESIDENT agreed that the fright caused by a badly administered anaesthetic might easily lead to the development of night terrors. Ethyl chloride was the ideal anaesthetic, especially if given by the open or semi-open method as these allowed of adequate supplies of air. He believed ethylene to be a better anaesthetic than gas and oxygen despite its inflammability and unpleasant smell and it might turn out to be the ideal anaesthetic for children. Chloroform was certainly contraindicated, and he wished to draw the attention of the meeting to three specimens of fatty liver removed from patients who had died after the administration of this drug or a mixture containing it.

Dr W. J. MCCARDIE (Birmingham) joined issue with the opener on the wholesale condemnation of chloroform, which he considered still had a place in the anaesthetist's armoury for such cases as needed operations on the eye, brain, or mastoid. Ethyl chloride had its dangers, but was safe if given on an Ormsby mask with equal quantities of ether. Instead of inserting Gargec tissue under a face-piece he used the old-fashioned leather mask. He asked what was the position of the registered but unqualified dentist in the matter of giving ethyl chloride, as he had not had any training in the administration of the drug. In view of the cost of ethyl chloride it would be well to know how much was needed for its administration by the open method. He was quite prepared to find that ethylene might be of use in children.

Dr I. W. MACILL (London) asked why intratracheal anaesthesia was not more often used in children. He had employed the method in babies a few weeks old with satisfactory results, and thought it without danger. He used a No. 9 double French catheter in these cases.

Dr DIETRICHSON BEAUM (London) was interested to hear that chloroform was out of fashion. In her early days she had administered many thousand anaesthetics for operations on the tonsils by the closed ether method with a Clover inhaler without ill effects, despite the fact that no atropine was given beforehand.

Dr HUGH PHILLIPS (London) questioned whether tact alone could deal with a refractory child, if so he would be pleased to hear the receipt. He preferred shock tactics in these cases—to knock out the patient as quickly as possible. He also thought that atropine did not act as well when given by the mouth as when given hypodermically. The danger of faint from the giving of a hypodermic injection reflected on the training of a nurse. He knew from personal experience that many nurses did not know how to give a hypodermic injection properly and painlessly. He thought the best method of anaesthetizing in special cases was to use gas and oxygen with local anaesthesia. In rectal cases over 3 years of age he recommended that 1/10 grain morphine should be given with the atropine to prevent after-pain. He doubted whether chloroform could be placed entirely on the shelf, it was useful in cases of bronchoscopy and in operations for squint. He believed in inducing with ether and adding a little chloroform later, this was also useful in tonsillectomy cases. In his experience rectal ether was a failure in children, as the oil ether was not retained long enough to produce anaesthesia.

Dr H. W. FATHERSTONE (Birmingham) said that even ethyl chloride was not always sufficient for a dental operation. He had recently reapplied the mask in such a case with the addition of 2 c.c.m. of ethyl chloride. The patient passed into a deep anaesthesia lasting five or six minutes. He wished to know why such a small addition of anaesthetic should have produced such a marked result. He had used rectal oil-ether with satisfactory results in a girl of 12 suffering from exophthalmic goitre.

Dr Z. MENNELL (London) said he intended to try the administration of atropine by the mouth. He asked what depth of anaesthesia and how much ethyl chloride should be given in any one case. He named the advocates of chloroform of the danger of using this drug in decompression cases where there was much tension, a fatality was bound to occur. He believed that with skilled operators, not necessarily surgeons, an anaesthetic was quite unnecessary for circumcising children under 14 days of age.

Dr R. J. CRAVER (London) endorsed the opener's remarks with regard to ethyl chloride. He inquired whether its use was prohibited in certain hospitals. He used it for dental operations in children by the open method and found vomiting thereby diminished. Nasal gas he found quite satisfactory for most children, and approved of endotracheal methods. He thought ether and oxygen preferable to open ether for children.

In reply, Dr SINGH said he had a horror of chloroform for children. He preferred closed to open ethyl chloride for dental extractions, as it gave a longer anaesthesia, but a free airway was essential. He believed that ether could be used satisfactorily for ophthalmic operations. He had no experience of endotracheal methods in children. Salvation at the beginning of an operation was due to the atropine not having been given sufficiently early, in such cases, if the mouth was well swabbed out, salvation did not occur. He understood that the average cost of an operation at the Great Ormond Street Hospital was 1s 9d. He was not able to say exactly how much ethyl chloride was needed for each case as this depended on the case. The important thing was not how much of the drug was poured out, but how much was taken in by the patient and this could only be regulated by careful observation of the clinical signs of anaesthesia.

THE PREVENTION OF SCHOOL COLDS

At a meeting of the Medical Officers of Schools Association on November 6th, with Dr L. R. LEFEBVRE (Halesbury) presiding, a discussion took place on the prophylaxis of common colds in schools.

Dr A. I. SIMER (Rugby) said that the prevention of these affections, which had such a hindering effect upon school work, and possibly such a damaging effect upon the future health of the individual, resolved itself into keeping the children out of the way of infection and raising their immunity. An infection was usually brought into school at the beginning of term by children who had left home with a cold or whose resistance had been lowered by the late hours and festivities and outings of the last week of the holidays. An appeal might be made on this point to parents, but to be of any use it must be addressed to them individually and periodically. Attention must be paid to the cleaning and ventilation of the schoolrooms, and fires should be lighted a few days before the pupils were due to return. It was impracticable to provide in a school a separate dormitory for each boy, and such a separation would be inadvisable on social and moral grounds, but there might very well be fewer beds in each dormitory and a stricter rule in the matter of spacing. More attention should be paid to tidiness both of place and person. His impression was that girls' schools suffered less from influenza and similar epidemics than boys', and this he attributed to the greater care taken in girls' schools in the matter of tidiness and the supervision of living quarters. The provision of adequate footwear was also very important. With regard to the raising of immunity, in some individuals immunity was naturally high, and even before puberty they passed through epidemics unscathed, on the other hand he had known two well marked attacks of influenza quite apart from relapses, to occur in the same

individual within three months. So far there had been no combined effort on the part of medical officers of schools to tackle prophylactic vaccination. He urged that in many schools as possible should join in one concerted experiment. It would be well if those who agreed to such an experiment would send cultures from the nasopharynx or throat or specimens of sputum to one laboratory in order to have a vaccine of local origin prepared, leaving it to the pathologist to use and incorporate as many strains as his experience led him to consider necessary. He hoped that some such work would be undertaken under the supervision of a committee of the association.

Dr G E FURD (Christ's Hospital) said that it would be of great value if in public schools there could be enforced a system of vaccination with either an influenza or mixed vaccine twice a year, but he was afraid there would be practical difficulties. He had carried out two mass inoculations at Christ's Hospital. The first was in the winter of 1918, when he inoculated 633 boys—about 73 per cent of the school—with seven or eight strains of the Pfeiffer's bacillus which was grown from an epidemic which was then going on in St George's Hospital. At the time of the vaccination there was no case of influenza in the school. He was told that he must expect about 10 per cent of the cases to react fairly violently, he therefore arranged for the taking of temperatures systematically for a few days round about the period of the vaccination, all games were stopped, and on complaint of headache or anything else a boy was sent for inspection to the infirmary. There were 186 local reactions (swelling in the arm), 35 focal reactions (sore throat, resuscitation of an old ear discharge, or acute cold), and one general reaction (fever and malaise). The cases of focal and general reaction were admitted to hospital, and all recovered in a few days. There were no cases of influenza following in the school, though there were several cases among unvaccinated members of the school staff living in the precincts. At the second mass inoculation, in 1920, when 762 boys were inoculated, the results were even better with regard to reactions, and again no cases of influenza occurred in the school. The immunity appeared to be brief, in the term following the one in which the first inoculation was made there was an epidemic of 300 cases of influenza or pyrexia of unknown origin, about six times the normal term average, though none of them were serious. It appeared also that if something like 70 per cent of a school population were protected in this way, those protected sufficed to protect the unvaccinated. It was possible also that a wider non specific immunity was given even by a specific vaccine such as the one used in these instances. The difficulty of these mass inoculations was greater than in the case of inoculation against typhoid or dysentery by reason of the fact that whereas in these latter diseases perhaps none of the inoculated would be carriers, in the case of influenza or pyrexia of unknown origin the carriers might number 30 per cent of the inoculated. It was also rather a big undertaking to restrict the liberty of the school in the manner necessary for carrying out of the inoculations. There was another method by which the resistance of the individual could be assisted—namely, by nasal drill and definite instruction in personal hygiene. Before he introduced nasal drill there was an average of 80 cases a term of pyrexia of unknown origin or similar conditions, since the introduction of the drill the average had fallen to 50. If these matters of personal hygiene were properly attended to a great deal in the way of prevention might be done. He would not suggest that they should supersede experiments in vaccination, but he saw many practical difficulties in getting concerted action for such experiments.

Dr G L BURNING (Tonbridge) said that in his school regular inoculations had been carried out for five or six years. In the first year the results were sensational. Over 80 per cent of the boys were inoculated, and the results were most evident even to the superficial observer. At school chapel, where previously the preacher, especially if his sermon was dull, could scarcely hear himself speak, there was scarcely a cough to be heard. In subsequent years the proportion of those inoculated was not quite so high, but he did not think it had ever fallen below 65 per cent. The

vaccine used against colds was that prepared under the instructions of Sir Almroth Wright, and issued by Parke, Davis and Co. Not very large doses had been used the first dose being 0.2 c.c., followed by 0.4 to 0.6 according to the size of the boy. In order not to discourage inoculation it was thought better to underdose rather than overdose, and good results had been forthcoming from doses however small. It was essential that the inoculation should be carried out within the first few days of the term. He agreed that the carelessness of boys with regard to hygiene was a contributory cause of colds, and inadequate footwear—much of the leather of the present day being more like blotting paper—must also be held responsible. A few unhealthy throats in a school sufficed to start an epidemic.

Dr S P HUGGINS (Wycombe Abbey) said that he had found some good from the Wright vaccine, but there was difficulty with parents in carrying out the system as thoroughly as might be wished. In one inoculation, out of 117 girls only six got a temperature above normal, and only one of the six had a really bad cold in the head and some bronchial catarrh. The majority of children showed a very slight reaction after the first dose, and none after the second and third. He would like to know whether it was desirable to give a third dose after a rather sharp reaction following the second. Games were not stopped during the inoculating period, except for those who showed temperatures. He had always stuck to the old formula for antiscorbutic vaccine, in the new formula the staphylococcus had been dropped, but he thought the staphylococcus very important, it existed in very many of the nasal discharges. The result of the inoculation was to make the school all round much more free from colds and minor sickness. The best time to start inoculations was at the beginning of the Michaelmas term. If the Lent term were chosen one was liable to begin at a time when there were already a good many children in the school suffering from colds, and if care were not taken severe reactions might be set up.

Dr MISS DOWNING hoped that if any committee was appointed it would consider the case of day schools as well as boarding schools. In girls' schools there was less influenza than in boys', partly because girls were rather more cleanly, and their clothing also was more washable. The difference in cleanliness between boys and girls appeared to arise after they began to go to school, which rather suggested that schools had in this respect a corrupting influence upon boys.

Dr LEWIS NASH thought that any evidence with regard to the value of inoculations should be collected and collated very carefully by a committee, which should submit recommendations to a general meeting of the association. It was not wise to rush this matter. Any step must be taken carefully on account of public prejudice. On the general question of the prevention of colds, he believed that cold and wet feet had a great deal to do with causation. If school floors could be warmed so that children would no longer have to sit with cold feet at lessons much good might be done. In Lancashire the people were extremely immune from colds although they worked in factories in a humid atmosphere, and this might be due to the fact, largely, that they wore clogs and thus kept their feet warm from morning until night.

Dr JAMES KIRK also urged the necessity for the careful collection of evidence before a definite line was taken by the association on the subject of prophylaxis. At present there appeared to be no way of standardizing these administrations of vaccine. Some children did well with one injection, others required three.

Dr OCTAVIA LEWIS urged the importance of nasal drill. In one of the schools she had visited in the North of England the headmistress insisted on the girls having a clean handkerchief and a pocket in which to keep it, and that school, although situated in a foggy and unhealthy locality, had practically no loss of time from colds or other epidemics.

Dr S H A LAMPERT (Harrow) said that he was not at all clear that the difference in the incidence of colds as between boys and girls was a matter of personal cleanliness. In the preparatory schools the incidence was about the same for both sexes. It might be that in boys' schools the pupils

were accustomed to go to football and other sports in damp weather without enough attention being paid to boots and overcoats.

Dr J LAMBERT (Wellington College) said that he had had a good deal of experience in individual cases with the St Mary's vaccine. He estimated that from 70 to 80 per cent of those inoculated remained free from colds for from three to nine months, in some cases, however, the protection was certainly very limited. Inoculation was rather a "shot in the air," but it was worth trying. He had rarely found a bad reaction follow the use of this vaccine.

The meeting agreed to recommend the council of the association to appoint a subcommittee to investigate the best methods of preventing colds and infectious eruptions in schools.

SIGNIFICANCE OF OPTIC NEURITIS

A MEETING of the Royal Medico-Chirurgical Society of Glasgow was held on October 23rd, when the President, Professor ARCHIBALD YOUNG, in the chair, opened a discussion on optic neuritis and its significance.

Professor Young referred to the varying applications of the term "optic neuritis," and asked a number of questions on which he hoped the discussion might throw some light. What did the ophthalmologist really mean by optic neuritis? How was one type differentiated from another? Could the type due directly or indirectly to intracranial tumour be recognized with certainty from other conditions of the optic nerve? What was papilloedema and in what special types of intracranial tumour was it met with? How was papilloedema produced? Did ophthalmologists recognize in the anatomical relationship of the third ventricle to the optic tract any preponderating influence in the production of optic neuritis in cases of intracranial tumour? Could the ophthalmologist tell them, as surgeons, at what stage the condition had advanced so far that operative interference held out no hope of recovery of the nerve and the saving of some degree of vision? Such questions were of great importance from the point of view of the general physician, the neurologist, and the surgeon, and it would be valuable if, arising out of the discussion, a finer adjustment could be obtained regarding their views of the types, degrees, and stages of what was one of the most important signs in the diagnosis of intracranial conditions. Professor Young urged the importance of the early recognition of the presence of optic neuritis while the chances of saving vision were still reasonably good. He asked if it was possible in the very early stages to arrive with any degree of certainty at an authoritative distinction between the changes in the nerve resultant on a developing intracranial tumour and those which might be caused by other conditions, such as intracranial or extracranial suppuration, meningeal conditions, cardio-vascular disease, thrombosis, retrobulbar neuritis, injury in its different forms, tubercle, syphilis, or by any of the poisons which affected the optic nerve, such as lead, quinine, and arsenic.

Dr H WRIGHT THOMSON reviewed briefly the terms in common use in connexion with inflammation or congestion of the optic nerve, including retrobulbar optic neuritis, optic neuritis, papillitis, papilloedema or choked disc, neuroretinitis, and optic pseudo-neuritis. Having defined these terms, he divided optic neuritis as seen by the ophthalmoscope in the light of recent pathology into two classes: (1) A true neuritis—namely, an inflammation of the nerve head, to which the name "papillitis" was given. (2) Papilloedema, where the changes were due to oedema and histological evidence of inflammation was absent, or so slight as to be negligible. Considering next the mechanism producing papilloedema, he quoted Sir John Herbert Parsons's view that the predominant factor was increased intracranial pressure, and referred to the three common theories as to its production: (a) impediment to the return of lymph along the intracranial space of the nerve, (b) impediment to the venous return, and (c) arterial anæmia, leading to altered conditions of osmosis at the nerve head. Discussing the ophthalmoscopic picture, the speaker quoted De Schweinitz's modification of Marcus Gunn's description of the six stages in the development of papilloedema. While a true typical neuroretinitis was easily distinguishable from a true papilloedema, there were many cases in which it was

impossible to say whether the ophthalmoscopic picture was papilloedema or neuroretinitis. In cases which had been under observation for some time, the development of the fundal picture might establish the priority of the relative severity of the retinal and papillary changes, but unfortunately it was notable how frequently the discovery of the ocular condition directed attention to the more important primary lesions, such as intracranial tumour, or albuminuria. Finally, Dr Thomson referred to the extraordinary variation in the appearance of normal discs in different persons, and uttered a warning against the diagnosis of inflammation or oedema in the absence of any definite swelling or haemorrhages, especially if both fundi showed the same picture. He concluded by discussing the value of the commoner subjective symptoms, such as dimness of vision, variation in the field of vision, small scotomata, and peripheral restriction.

Dr A J BALLANTINE, discussing the part played by papilloedema in the diagnosis, prognosis, and treatment of medical and surgical cases, referred to some interesting figures obtained from the records of routine eye examination in (a) a general hospital and (b) an eye hospital. In 1,100 cases examined without selection in the wards of the general hospital, papilloedema was found in 5 per cent, intracranial tumour, renal disease, and tuberculous meningitis providing the vast majority of examples. Among 6,000 cases seen at the eye hospital, only 0.5 per cent showed papilloedema, and the majority belonged to two classes, renal neuroretinitis and acute retrobulbar neuritis. In private practice papilloedema of any form or degree apart from albuminuric neuroretinitis was extremely rare. In regard to the value of papilloedema as an aid to diagnosis, he had found that chronic degenerative types of renal disease provided the largest number of examples in the general hospital series. The ophthalmoscopic picture varied from a moderate degree of oedema, affecting equally the optic papilla and the general retina, to the more striking form in which all the details of the disc were obscured and parts of the retinal vessels buried by the extensively swollen papilla. In all cases, however, it was the rule to find haemorrhages, grey patches of exudate, and clusters of glistening spots, or the characteristic macular star. Occasionally a true choked disc was seen in such cases, and such a picture with severe headache and sickness might even in the presence of albuminuria and other evidence of kidney trouble, raise the question of cerebral tumour. Intracranial tumour came next in order of frequency, but few of these cases were followed for any length of time. In tuberculous meningitis (confirmed by necropsy or by the presence of choroidal tubercles), of which 11 examples were seen, the optic neuritis resembled the papilloedema of intracranial tumour rather than the optic neuritis of renal cases. Of a series of 61 cases of cerebro-spinal meningitis 5 showed optic neuritis, and in 5 cases of hemiplegia papilloedema was present. Dr Ballantine referred also to the presence of optic neuritis in encephalitis lethargica. In the eye hospital cases not a single example of choked disc or of intracranial tumour was found in over 6,000 cases. Papilloedema occurred most frequently as part of a neuroretinitis either frankly renal or arterio-sclerotic in type. Acute retrobulbar neuritis was surprisingly common, but differed from the classical description in that the cases presented a notable degree of papilloedema indistinguishable sometimes from that due to early cerebral tumour or from that of renal neuroretinitis. They resembled each other and the typical cases of acute retrobulbar neuritis in giving a history of rapid and profound loss of vision, sometimes associated with severe headache. The ophthalmoscopic picture showed a definite optic neuritis with oedema of the papilla either unilateral or bilateral. In all cases a tendency to recovery was manifest with usually a more profound central defect, especially for coloured vision. In one or two of such cases definite disease of the ethmoid or sphenoid sinuses was detected, and in the differential diagnosis a full investigation of such possible sources of infection was advisable. Referring to the question of trauma as a cause of optic neuritis, the speaker quoted two cases in which papilloedema occurred, with other evidence of injury of the base of the brain. This was attributed in the one case to oedema of the brain following concussion, and

such was the dread of catching the natural small-pox that the practice of inoculation continued to gain favour, and the Princess of Wales, having seen the operation successfully performed upon some charity children, decided to have the two young princesses inoculated. The operation was again successful, and this example of royalty did much to make the new practice fashionable. Results were not always satisfactory, however. Sometimes, for reasons not properly understood, the resulting attack, instead of being mild, was very severe and even fatal. There were 17 deaths among the first 900 cases inoculated, or about 2 per cent. Thirty years after inoculation was first introduced the Prince of Wales contracted small-pox in the natural way, and it was then decided to inoculate the other two royal children. About this time the College of Physicians issued the following declaration in favour of the practice:

"The College, having been informed that false reports concerning the success of inoculation in England have been published in foreign countries, think proper to declare their sentiments in the following manner:—namely, That the arguments which at the commencement of this practice were urged against it have been refuted by experience, that it is now held by the English in greater esteem and practised among them more extensively than ever it was before, and that the College thinks it to be highly salutary to the human race."

It was some ten years after this declaration that a new epoch in the history of inoculation was introduced through the success attending the practice of Mr. Daniel Sutton. Sutton at first surrounded his method with much mystery, and advertised that he possessed certain secret remedies which ensured the attack being always very mild. A clergyman friend, supposed to have been employed by Sutton, preached sermons extolling the success of Sutton's method and claiming that amongst 20,000 cases inoculated by Sutton and his assistants in three years there had not been one death which could fairly be attributed to the operation. Sutton was certainly very "successful" from the financial point of view, and soon made a fortune out of inoculation. But even allowing for his own and his friend's exaggeration, his results certainly were better than had previously been obtained, and his method became known as the "Suttonian." It is not certain to what this improved result was due. His chief departures from established usage were (1) to take his "matter" for inoculation very early in the life history of the pustule, even before the lesions had become pustular, and (2) to allow his patients to expose themselves freely to fresh air instead of keeping them closely shut up indoors.

Dimsdale, another famous inoculator and one of the first to follow Sutton, appears to have attached little importance to the first point. Such was Dimsdale's reputation that he was summoned to Russia to inoculate the Empress. He obtained his "matter" on this occasion from a natural case in a child (in St. Petersburg) in whom the eruption was just beginning to appear. The result was entirely successful, and the Empress was able to return to Court sixteen days after the operation. As a reward for his services Dimsdale was made a baron of the Russian empire, appointed Counsellor of State and physician to Her Majesty, and granted a sum of £10,000 together with an annuity of £500. In a treatise on inoculation Dimsdale described the points in which, as the result of fuller experience, he had modified his earlier practice. He had come to the conclusion, he said, that it was hardly necessary to prepare the patient beforehand or to enjoin restriction of diet. He did not prescribe special medicines, and had become more sparing in the use of purgatives. He preferred the lancet to the needle, using the smallest puncture possible. If no suitable patients were available from which to obtain matter, he employed dried matter which had been stored.

Trouseau, one of the latest of those to write from personal observation, described the phenomena of inoculated small-pox as follows:

At the act of insertion of the virus a small red pimple appears on the second day. By the fifth day it has become an accumulated vesicle but is depressed in the centre. On the sixth or removal of unhealthy matter a pustule with an areola appears, another matter, and might be a pustule with an areola as a modern development. No previous centre and bluish to arise till the latter part of the eighth day. The pustules appear on the eighth day and within the fortnight and successive

crusts form and separate. Constitutional symptoms—head ache, vomiting, rash, etc., begin on the ninth or tenth day and from the eleventh to thirteenth day a specific eruption shows itself following the course of modified or normal small-pox.

It was difficult to say (Dr. Millard continued) to determine whether inoculation as practised in this country in the eighteenth century was, from the point of view of the whole community, beneficial or the reverse. No doubt, in view of the serious menace of natural small-pox, it benefited the individual, but, on the other hand, it tended to spread small-pox to those who might otherwise have escaped, and it had been alleged that by thus increasing the prevalence of natural small-pox it actually increased rather than diminished the total number of deaths. After the introduction of vaccination inoculation was soon superseded by it. The underlying principle of both inoculation and vaccination was the deliberate infliction of an attack of disease in a mild form upon a healthy individual in order to protect from the possibility of a more severe attack. It was a form of insurance, but whether such insurance was good policy or not clearly depended upon (a) the amount of the premium, (b) the gravity of the risk insured against, and (c) the duration of the protection conferred. As regarded (a) vaccination was an undoubtedly less serious matter than inoculation, but the duration of the protection it conferred (c) was certainly much less. The chief consideration to-day, however, was that the risk to be insured against—the menace of small-pox—was negligible compared with what it was in the eighteenth century. It must be concluded, therefore, that the case for vaccination in the twentieth century was very much weaker than was the case for inoculation in the eighteenth.

NEWPORT MEDICAL SOCIETY

At a meeting of the Newport Medical Society on October 28th, the President, Dr. S. HAMILTON, in the chair, Dr. H. R. BLURITT gave an address on mental deficiency in which he briefly explained what constituted mental deficiency, its incidence in the population. Mental deficiency was one of the greatest sociological problems, and it was the duty of the medical profession to strive for its solution. The private practitioner could help greatly by using all his influence to prevent marriage of the unfit. He could also help to mould public opinion in favour of urging Parliament to pass measures for some form of segregation.

Mr. RUFUS THOMAS and Dr. T. GUYAN JAMES showed a case of genital maldevelopment in a newborn female child in whom the early embryological condition of a cloaca communicating with the bladder in front and the rectum behind had persisted. There was no urethra and no anus. Urine and faeces were passed into the cloaca and thence to the surface. Both labia majora were well developed and at the posterior end of the left labium was a lipoma the size of a small walnut. The vagina was present with a rudimentary cervix, and a post-anal dimple appeared to be connected with the tip of the coccyx. A certain amount of control of both urine and faeces had been developed in the fortnight which had elapsed since birth.

Dr. L. E. ACOOM gave an account of a rare case of abnormal pregnancy which proved to be one of full-term ovarian foetation. A primipara, aged 33, complained of great pain, distension, and inability to lie flat in bed during the latter months of pregnancy. As he was unable to determine the position of the foetus or the nature of the presenting part, even under anaesthesia, he referred the case for x-ray examination. The skiagrams showed a fully developed foetus lying in an extremely irregular and distorted position. He performed Caesarean section and found it was a case of extruterine gestation. The uterus was still in the pelvis, the right Fallopian tube was flattened and stretched over the gestation sac, and the tissue of the right ovary was thinned out and constituted the outer layer of the sac. He believed it was a genuine case of ovarian foetation. The foetus was dead, but the mother made an excellent recovery. Dr. T. I. CHAMBERS showed and described the three skiagrams which he obtained of the case prior to operation. He thought they were unique, and possibly the first x-ray photographs on record of a case of pregnancy of this nature.

Reviews.

FOETAL SYPHILIS

In a recent study of the subject of foetal syphilis Professor EKHORN divides the children born of syphilitic mothers into four classes, basing his conclusions on statistics furnished by Professor THOMSEN of Copenhagen. The first class contains the healthy children, some 39 per cent of the total number, free from syphilis at birth. The second class contains the cases of what he calls "post-natal syphilis," the children being infected but apparently free from infection at birth, and developing signs of it only some weeks, as a rule, later. The third class consists of cases in which the infection is manifest at birth and the child is alive, these are cases of foetal or pre-natal syphilis, having no doubt been ill *in utero* for several weeks, and they all die soon, usually in a few days or less. The fourth class is that of the stillborn children with foetal syphilis.

The children in the last three classes described above are all cases of congenital syphilis. Syphilitic endometritis was seen in 70 per cent of the cases, it took the form of foetal and later diffuse infiltration of the basal and parietal decidua with leucocytes, often accompanied by invasion of the chorion and amnion also, and in the foetal placenta going on to the formation of abscesses, gumma formation seems to be unknown. The more extensive the maternal endometritis the greater the chance that the child will be infected also, though there is no parallelism between the extent of the infection in the endometrium and its extent in the child at birth.

Professor EKHORN argues that the course of foetal syphilis (classes 3 and 4 above) depends on the age or degree of maturity of the children at the time when the infection takes place *in utero*, the older the foetus the less malignant the syphilitic infection, while the strength of the infection is a matter of indifference. In its early days the unborn child has no resistance to the infection, and has acquired only a little by the time it is born, while adults may be described as having good resisting powers. Hence the syphilitic spirochaetes multiply in the foetus and may be found in enormous numbers in it, while in the maternal placenta they are always very hard to find. In the still-born children the evidences of tissue reaction to the syphilitic infection are much scantier than in the foetuses of class 3. The development of such things as abscesses, splenic hyperplasia, hepatic hyperplasia, and sclerosis of the lungs and pancreas, all evidences of tissue reaction, is hardly met with before the last two months of intra-uterine life, and receives a long survey from the author. Discussing syphilitic excretion in the foetus, Professor EKHORN classes it among the reactive processes, and describes it, not to degeneration, but to the action of an antitoxic or anti-spirochaetal ferment analogous to that found by Lundbeig in tuberculous granulation tissue, and produced in all probability by the granulation cells and epithelioid cells. The immediate cause of death in foetal syphilis is said to be evident paralysis due to spirochaetal toxins. Regarding the subject from an evolutionary point of view, Professor EKHORN concludes that the lesions of foetal syphilis are so much more severe than those of syphilis in the adult because foetal syphilis is a disease of undeveloped organs that have not had time to develop any but rudimentary powers of resistance.

The book ends with a brief bibliography. It should be read by all medical men and pathologists who are interested in the subject of congenital syphilis. The author expresses his views with considerable force and not a few repetitions, and throughout his book he refers to the spirochaetes of syphilis as spirochaetes or bacteria indifferently. Spirochaetes are by definition, coil-shaped organisms, and bacteria stick-shaped, to call spirochaetes by the name "bacteria" is perhaps a little unfortunate, for it seems inevitable to call up pictures of Sir Harry Lauder's walking-stick.

* *Syphilis Fetusum*. By C. O. EKHORN. Acta Medica Scandinavica Supplementum VII. Stockholm. P. A. Norstedt and Soner. 1925. (Med. 8vo pp. 145.)

ORTHOPAEDIC SURGERY

By operative orthopaedics we understand Dr STEINDLER to mean only such proceedings as involve free division of the skin and exposure of the parts to the eye of the surgeon, although he also describes the operation of subcutaneous tenotomy. It is to be presumed that he would not classify the reduction of a congenitally dislocated hip by the method of Lorenz as an operation. From a cursory survey of this book the student is likely to carry away the impression that bold cutting operations are the main occupation of the modern orthopaedic surgeon. But in his opening chapter Dr Steindler is careful to impress upon his readers the caution that "there is no room in operative orthopaedic surgery for any method unless it be applied with the strict understanding that it shall constitute merely an incident in the treatment." In order that his readers may see orthopaedic surgery in its true perspective, it will be necessary for Dr Steindler to publish a companion volume devoted to manipulative and bloodless treatment and the after-care of those cases which are dealt with in this volume. In discussing operations on tendons Dr Steindler unwittingly discloses how strong is the German influence in some American schools. Although the classical work of W. J. Little on club-foot appeared in 1839, he ignores it, and gives credit instead to a work by Dieffenbach, which appeared three years later. Such familiarity with German surgical literature should have prevented him misspelling Stromeyer as Stromyey. His statement that "In the early pre-antiseptic era even the subcutaneous tenotomies constituted a formidable operation which was often followed by suppuration and other accidents" is of variance with recorded and well known facts. It was the almost complete immunity of the operation from such accidents that made its use general until and even after Listerism became the rule, but if the incision for tenotomy of the tendo Achillis were often as free as that depicted in Plate III, we can well believe that without Listerism appalling results would have ensued.

Dr Steindler relies considerably upon statistics, and gives his own as well as others' figures, but the value of such data is diminished by the persistent difficulty of ascribing what exactly is meant by such terms as "good," "fair," etc. There is no such ambiguity about the caption "Died." The chapter on cinematization might well have been omitted. In this country at least, and we believe in other European countries, the method has been abandoned as of little use or no practical value.

The student who wishes for information as to the conduct of any open orthopaedic operation will find this book of use, for the drawings are clear and well designed for their purposes, but its value would have been greater had the writer's modesty allowed him to afford rather more guidance to his reader in the choice of methods.

Dr SEVER's book on orthopaedic surgery for students of medicine differs widely from the subject of the preceding notice. It is difficult to classify, for while its title suggests that it is intended for those with knowledge of anatomy and physiology, its style and the language seem more suited to the lay reader. The greater part of the book is almost elementary in its simplicity and avoidance of technical detail, but some subjects are treated more fully than others. Among these are tuberculous joint disease and specially birth-piles of the shoulder, which latter and spritic piles, oddly enough, are included in the section on infantile paralysis. There are few directions for the performance of operations, but Dr Sever's own procedure for the relief of contraction in birth-piles of the shoulder is described in considerable detail. Dr Sever argues well that in recurrent dislocation of the shoulder-joint the muscles, and not the capsule, play the chief part in its causation and its cure. The pages on back troubles and spinal curvatures are practical. The section on spastic

1. *Textbook of Operative Orthopaedics*. By A. Steindler, M.D., F.R.C.S. New York and London: D. Appleton and Co. 1925. (Med. 8vo pp. xv + 403, 83 plates, 30s. net.)

2. *Textbook of Orthopaedic Surgery for Students of Medicine*. By James Warren Sever, M.D. New York: The Macmillan Company, London: Macmillan and Co. Ltd. 1925. (Med. 8vo pp. xviii + 353, 169 figures, 20s. net.)

pnualysis is very meagre. The characteristic deformities of Little's disease are very shortly described, but no attempt is made to specify the morbid anatomy of the defects which are the foundation of the symptoms. The surgical treatment is dismissed in seven lines, and Stoffel's operation (wrongly printed as Stocflo) is vaguely referred to in another six as likely to be useful, but a reader previously unacquainted with the procedure could hardly learn from what is here said the principles on which the proceeding is based, and still less how it is to be carried out.

The last chapter contains a great deal of practical value in instructions for the preparation and fitting of various appliances. The Bradford abduction splint for hip disease is well described, and so are the knock knee irons, which appear to be used in America in place of the simple wooden ambulatory splints which satisfy many British orthopaedic surgeons. Valgus shoes and club foot shoes are described at considerable length, but unfortunately without illustrations. The technique of plaster-of-Paris casts and splints and jackets is as practical as one would expect from the Boston school. Celluloid splints and jackets are also described, as are Thomas's splints and steel spinal supports. The great St Bartholomew's surgeon deserved much more than a knighthood, but Dr Sever should not call him Sir Percival Pott. Charles Beevor's work is sufficiently well known for his name to be correctly spelt, and not Beevor.

DIXON'S "PHARMACOLOGY"

Dr W E Dixon's *Manual of Pharmacology*, of which the sixth edition* has just appeared, is well known as one of the most popular student's textbooks in this subject. It is only three years since the last edition appeared, and no extensive alterations in the general arrangement have been necessary. The new edition, however, is a little longer than its predecessor, and a number of new illustrations have been introduced. The final chapter, which deals with cod-liver oil and internal secretions, has been enlarged and contains some interesting photographs showing the effect of lack of vitamin A on the development of the bones and teeth.

The *Manual* is intended primarily for students who in this country study pharmacology before or at the commencement of their clinical work, the author, therefore, with reason confines himself chiefly to the experimental aspect of the subject. We think, however, that the book would be improved if more were said regarding the practical importance of the experimental conclusions. For example, the author discusses carefully the action of alcohol on the circulation and shows that under certain conditions alcohol can produce a very slight rise in blood pressure, and the conclusion is that "alcohol, then, has some title to the term circulatory stimulant." It is not, however, said whether there is any reason to suppose that alcohol can produce in man a rise in blood pressure sufficient to be of any therapeutic importance. The difficulty in applying laboratory results to therapeutic problems is well known, and it would seem desirable to help the student as far as possible to bridge this gap, for otherwise he may fail to realize that pharmacology has any bearing at all on therapeutics.

The special feature of the *Manual* is the clear manner in which the main actions of drugs are described, these descriptions, aided by the abundant illustrations, will enable students to form a very clear conception of the subject.

RADIOLOGICAL EXAMINATION OF THE MALE URETHRA

The Radiological Examination of the Male Urethra,⁵ by Kohnstam and Cave, is a short monograph giving in detail the technique necessary in this examination, together with the results it yields in pathological conditions. While this is the first work to be published in England on this method

of investigation, much has been written by Continental and American authors since it was first attempted by Cunningham of Boston in 1910.

The small volume under review, which contains some eighty pages of letterpress and over sixty illustrations, is not intended to be a complete work on urethrography—a clumsy word—but an introduction to its practice and to the interpretation of the skiagrams reproduced. The method is to inject diluted lipiodol into the urethra, but the interpretation of the resulting skiagrams is not easy, owing to the various curves of the shadow. The illustrations consist of diagrams and of reproductions of skiagrams, but the latter are not very satisfactory or convincing. We may note that Figs 53 and 49 appear to be placed upside down.

The authors in describing their method state that they use only five milliamperes through the tube, and that the exposure varies from two to six seconds. As most of the radiographs have to be taken while the fluid is being run in, rapid exposure appears desirable. This calls for a larger output of x rays, and this, at the present day, is easily obtainable. The impression formed after perusal of the book is that the method is a means of diagnosis of comparatively little value, but that it might be of some use in supplementing the present means of investigation.

EARLY DIAGNOSIS OF ACUTE ABDOMINAL LESIONS

Mr Zachary Cope's book *The Early Diagnosis of the Acute Abdomen* has reached its third edition⁶—welcome evidence, not only of its intrinsic excellence, but also of the eagerness of the profession to profit by such an aid to better work. The volume might well be the breviary of the young surgeon in his unflinching daily study.

There are few changes in this edition, and that is well, for it is just sufficiently dogmatic, and refinements will lead to qualifications, limiting adjectives and adverbs, from which lightho the text has been comparatively free. Criticism, for this reason, must be restrained, especially as in all essentials the dogmas are sound.

Some surgeons might think there is more rejoicing over one case in which segmental pains display their proper distribution than over the ninety-and-nine in which no help is derived from a search for them, but at any rate this consideration makes for clear thought and is properly encouraged. The excellent "Form for acute abdominal cases" on page 21 might with advantage have an entry for "stools." It is a book of permanent value.

QUANTITATIVE CHEMICAL ANALYSIS

The Theory of Quantitative Analysis and its Practical Application,⁷ by Dr H Basset, supplies a want in analytical chemistry. Since the early days of chemistry an immense number of methods of quantitative analysis have been devised, and from time to time modifications have been introduced, some of these were aimed at saving of time or labour, others were intended to safeguard a principle of accuracy. In most cases the devices of analytical procedure were evolved before the theoretical views relating to them were fully elucidated. Chemical theories in mathematical form have usually had their birth in experimental work directed towards aims other than those of chemical analysis, and physics and physical chemistry have been the chief contributors. Practice and theory were thus only to be found in different contexts and places. We have hitherto met with no book in which they were directly conjoined in their reciprocal relation to each other. This book is written on the presumption that the reader already understands the principles of mass action and of ionization. Such an understanding is necessary, since the powers of mass and the products of ionic dissociation affect all quantitative operations, and there has been sometimes a tendency to assume that a knowledge of

⁷ *The Theory of Quantitative Analysis and its Practical Application* By Henry Basset D.Sc. Ph.D. Twentieth Century Chemistry, edited by Sir William Tilden F.R.S. and J. O. Philip F.R.S. London: G. Routledge and Sons Ltd. 1925. (Demy 8vo, pp vii + 308 15s net.)

these matters is alone sufficient for the understanding of the subject. An examination of the author's work, however, will show that quantitative analysis not only embraces a wider theoretical knowledge but offers many opportunities for the study of theoretical aspects which have not even yet been fully explored. The most easily pardonable fault in a book is that its contents should be limited to an epitome of the author's own experience. This volume conveys that impression, but in this instance the experience is extensive to a rare degree. Among the subjects he has selected for special consideration are the condition of ammonia in aqueous solution, the significance of colloidal chemistry in quantitative analysis, the amphoteric compounds, and coordination and solubility. Views are expressed in the discussion of these subjects which will contribute much to the understanding of the behaviour of substances in solution and reaction.

NOTES ON BOOKS

DR MAX BRAUN's textbook on the animal parasites of man is so well known to parasitologists that little need be said about its scope and purpose. In recent editions it has been divided into two portions. The first part, by Dr BRAUN, deals with the zoological side of the subject, while the second, by Dr SEIFERT, discusses the clinical aspect. In the first part of the sixth edition,⁸ which is before us, this arrangement is still adhered to, and only the parasites and their biology are considered. The subjects, however, rapidly becoming so large that it is necessary, in order that it shall be adequately treated, to have the various sections written by specialists. This has not been done in the present case, and so the treatment of the more modern developments is to a certain extent superficial and patchy. As is to be expected, the German work of recent years is considered in some detail. The British advances are, however, in many cases overlooked. Thus, for example, Ashworth's monograph on Rhinosporidiosis is not mentioned, while several other important papers are also overlooked. Many of the illustrations have now only a historical interest and might well be omitted, while a number could be replaced by the more modern and more accurate drawings available. The nomenclature leaves much to be desired, and a number of species are retained which modern workers consider to be invalid. The protozoan and helminth sections allotted 157 and 253 pages respectively. Only the actual entomological parasites are considered in detail—the "carriers" are only briefly mentioned—and the number of pages given to the insects and arachnids is about 75. There is a large and, despite several misprints, valuable bibliography. The book is, indeed, a useful compilation, but if it is to retain its encyclopaedic character there must be a further division of labour, and no time must be lost in preparing a seventh edition in order to incorporate the work of recent years.

An elementary textbook, dealing with public health, has been issued under the auspices of the Press Committee of the Middlesex Hospital. It is entitled *The Nurses Handbook of Hygiene*,⁹ and has been written by Dr L. E. H. WHITBY. Now that hygiene is included in the examination of the General Nursing Council for England and Wales it is important that a suitable manual should be available for candidates for this examination. This book supplies in an elementary and readable form the information a nurse should possess about the fundamental principles of public health. The figures and diagrams are clear; the only criticism that might be made is that the amount of magnification is not stated below each figure. A useful glossary of technical terms is added, and there is an index.

Dr A. E. HERTZLER's little book on *The Technique of Local Anesthesia*¹⁰ is based very largely on his own experience with the methods he employs and is therefore very practical. He is not an out-and-out advocate of local anaesthesia, and does not appear to use it as a routine for every occasion. In his own words, "It is the proper selection of method that marks the skilled surgeon and not his ability to do certain things with local anesthesia," and he lays much stress on the planning

of the operation. The first chapter, on the drugs employed, is well written and contains as much information as is likely to be asked for by a beginner. The technique of administration is dealt with clearly and fully, and then a chapter is devoted to general operations. Subsequent chapters are concerned with special operations, and the descriptions, which are clear, concise, and interesting, are illustrated by excellent semi-diagrammatic drawings in which the anatomy of the parts is clearly set forth and the direction of the injecting needle shown. The book is well got up and remarkably free from misprints, though there is one on page 75, where "subperitoneal" appears for "subperiosteal" infiltration in the description of operations on the extraction of teeth. We were also unable to find any warning of the danger of injecting the anaesthetic fluid into the blood stream, as may readily occur in attempts to anesthetize by the paravertebral route, if the fluid be injected without pulling out the piston of the syringe to see whether blood is withdrawn into the barrel of the syringe. If only for the possibility of doing this we agree with the author that the proper type of syringe to use is one with glass barrel and piston with metal mountings. The book can, however, be recommended to the beginner, as the teaching throughout is sound and practical, and no unnecessary space is taken up by anything in the nature of padding.

In *The Changing School*¹¹ Dr P. B. BALLARD gives an entertaining and suggestive account of modern tendencies in the education of children, and in particular of the movement towards freedom and individual work. The author is a teacher and examiner of large experience and a shrewd observer, and he writes with that freshness of style and breadth of outlook which make a book on a technical subject interesting to the general reader. This little work is in fact addressed quite as much to the parent as to the teacher, and medical men and women, whether as fathers and mothers or as family advisers, will find in its pages much to stimulate thought and clarify ideas on the problems of discipline and early education, both at home and in the school. Dr Ballard's attitude towards current psychology strikes us as sane and practical, it is a subject to which he pays a good deal of attention in several chapters. In his view the new psychology has not yet provided us with a new pedagogy. "It is true that the new psychology of the unconscious lends support in a general way to the modern educational trend towards freedom and individualism. But the two currents are independent. They merely happen to be running in the same direction." Of the Oedipus complex he remarks in the course of a footnote that the classical myths are extremely useful; you can make them mean anything you please. In a brief analysis of why some children misbehave themselves at school, he insists that "the teacher cannot fully understand the behaviour of the child at school without first understanding the behaviour of the child at home. For it is within the home, in the family life, that the roots of his temperamental troubles lie." Here, as in many other passages, the author will surely carry with him the medical reader.

Professor SIEGBAHN's account of *The Spectroscopy of X Rays*¹² is a book for crystallographers, mathematicians, and physicists. It gives a practical account of the subject from the purely technical beginnings to the most recent and important theoretical results to be deduced from the work done in many European and American laboratories, special references are made to atomic physics and full accounts are provided of the technique and apparatus employed. The author describes the direct conclusions drawn from the ever increasing mass of empirical material, but has chosen not to go very deeply into the consideration of the theoretical side of atomic and crystalline structure, as this has been recently set out very fully by Sommerfeld in his book on atomic structure and spectral lines. The translator, using the German edition of Professor Siegbahn's treatise, has done his work well, and so has the publisher. There are many tables useful for the practical worker in x-ray spectroscopy, and the literature of the subject is given very fully at the end of the volume.

The essay on dysenteric hepatitis and its treatment, by Dr PETRIDIS and the late Dr VALASSOPOLLO¹³ gives a good and complete account of the medical and surgical treatment of

PREPARATIONS AND APPLIANCES

amoebic inflammations of the liver. It is based on many years of experience at Alexandria in Egypt, and is divided into two parts. The first deals with the medical treatment, this consists in the subcutaneous injection of emetine in doses of 0.04 or 0.05 gram once or twice a day for four or five days together, this course of injections is repeated if necessary a few days later. Almost always the total quantity of emetine required for a cure is less than one gram. Were it not for the grave dangers attached to exploratory puncture of the liver Dr. Valassopoulos would employ it as an adjuvant in the treatment of amoebic hepatitis, because there is much evidence to prove that the local depletion of blood accelerates the processes of hepatic repair. The second half of the volume, by Dr. Pétidis, describes the surgical treatment of hepatic abscess, he states that the number of cases surgically treated in the Gicok Hospital at Alexandria in a year has fallen from an average of 25 to no more than 5 since the introduction of the emetine treatment. The book should be in the hands of all medical practitioners who have to deal with amoebic hepatitis.

Recently we recommended to readers interested in ships a delightful book by a medical writer, Sir Alan Moore, Bt., entitled *Fast Days of Mast and Sail*, which was described as an "Essay in Nautical Comparative Anatomy." Sailing ships are becoming more and more scarce, and Sir Alan Moore gave a picturesque account of a younger generation. But familiar and perhaps unknown to a younger contrast to the elegance of the sailing ship was a marked contrast to the life of the seafarer was compelled to lead, as the reader will find who turns from the essay in nautical anatomy to another book, *Fast Winds and Foul*, which gives a narrative of daily life aboard an American clipper ship. This astonishing account of life at sea was written by Mr. FREDERICK PERRE, who made the voyages described in the eighties and nineties of last century. It must be confessed that some of the stories told as though they had been embellished by the storied load as though they had been embellished by the repeated telling in the smoke laden atmosphere of a seaport tavern, but even though the tales may be exaggerated here and there the story is obviously founded on personal experience. The book gives a very vivid picture of the crowded ships and diversions, the bravery and humanity of the crew of a sailing ship making voyages lasting two or three months from port to port.

In his work on the pathological and social aspects of syphilis, which forms the latest addition to the series entitled "Science et Civilisation," edited by MAURICE SOLOVINE, Professor F. JEANSELINE has given an admirably lucid and concise account of present knowledge of the disease. The work is divided into two parts. In the first, which deals with the consequences of syphilis to the individual, an authoritative description, illustrated by original photographs, is given of the clinical aspects of the disease, including the latest methods of diagnosis and treatment, preceded by an historical sketch and sections on bacteriology, morbid anatomy, and experimental syphilis. In the second part the social significance of the disease is discussed, special attention being paid to such questions as the regulation of prostitution, the civil and penal responsibility for the spread of syphilis, infection, sexual education, individual prophylaxis, and the part the dispensary may play in combating syphilis.

The recently revised edition of the St. Mary's Hospital Pharmacopoeia contains a few changes in the titles of mixtures and some additions to the stock mixtures, hypodermic injections, and lists of dangerous drugs, common incompatibles, and caloric values of various foods. Copies may be obtained from the secretary, St. Mary's Hospital.

We have received a copy of Mr. G. S. COLEMAN'S *Calculations in Heating and Ventilation*. The author's object is to furnish senior students of this branch of engineering and their teachers with a practical textbook containing copious working examples. The book is too technical for the ordinary requirements of public health officers or students of domestic hygiene but it should prove of value to municipal and sanitary engineers.

PREPARATIONS AND APPLIANCES

Almata (a Food for Infants)
Messrs. KEE, ROBERTSON & Co. claim that their preparation "Almata" will be valuable in infant feeding. The manner in which the preparation has been placed on the market certainly presents a very welcome departure from usual custom, for the makers have subjected their product to rigorous scientific and clinical tests before introducing it to the general public. The most stringent test was one for vitamin content carried out at a well known biological laboratory. Rats were fed for three generations solely on "Almata," and the third generation still showed normal growth. This is a satisfactory supply of good evidence that *Almata* contains an adequate supply of vitamins A and B, and also all the mineral constituents essential for normal growth. The makers claim that the content of anti-scorbutic vitamin also is sufficient but this vitamin so readily disappears on keeping that it would seem wiser not to advocate the discarding of such easily accessible food adjuncts as orange juice even if the freshly manufactured article contains a full amount of this antiscorbutic vitamin. The results of chemical analysis show that *Almata* contains fats, proteins and carbohydrates in proportions similar to those occurring in human milk, that gastric juice does not produce a dense clot, and that the food is rapidly and completely digested by the pepsin and its pancreatic ferments.

Almata is prepared from egg yolk, butter, malto-dextrins, and dehydrated fresh fruit juice. The makers quote a number of clinical reports which show that infants fed on *Almata* develop a normal and satisfactory manner and charts are given which show that infants which have failed to gain weight on other foods have put on weight rapidly when fed on *Almata*. The makers claim that the ingredients and the conditions of preparation are controlled entirely according to instructions and advice received from leading living authorities on dietetics and infant feeding and that for three years *Almata* was submitted to exhaustive laboratory and clinical tests before being introduced to the general public.

The makers are to be congratulated on the care and expense which they have devoted to making their product as satisfactory as possible before introducing it to the general public. The composition of *Almata* represents many new ideas in the preparation of infant foods, and the reports quoted indicate that in practice the food has many advantages.

Cream of Nujol

Cream of Nujol with Agar is a pleasantly flavoured emulsion of oil of nujol and agar. Nujol is, we believe, an emulsion of liquid paraffin. The makers (the Anglo-American Oil Company, Albert Street, Camden Town, N.W.1) state that the product contains no cathartic ingredient or sugar. The preparation appears to be a palatable and convenient form of laxative.

A Series of Preparations

We have received the following preparations from the Chiron Aniline Company Ltd. (68, Upper Thames Street, London E.C.4): "Coramine" (pyridine β -carbonic acid)—Professor E. Sturmer Faust (*Lancet*, June 27th 1925) stated that this substance has an action on the heart similar to that of camphor. Coramine is soluble in water and therefore can be given by hypodermic injection more easily than camphor. The drug is recommended as a general cardiac stimulant. *Cibalgin* is a combination of amidopyrin and dinal (diallyl barbituric acid). It is intended as a non-narcotic analgesic and the makers express the hope that it may prove valuable as a substitute for morphine. *Cibalbumin* is an aqueous and limpid solution of egg albumen put up in aseptic form suitable for hypodermic intramuscular or intravenous injections. The preparation is intended for use in non-specific protein therapy.

"Diacene" is a new synthetic local anesthetic. In chemical constitution it is para-dialkyl-orthoethyl diphenyl diamidine. It is particularly intended as a local anesthetic in ophthalmology. Lussi (*Schweiz med Woch*, 1924, No 25) found that a 0.2 per cent solution was suitable for use in clinical practice. It is stated that the drug can be sterilized by boiling, and that instillations are non-irritant to the conjunctiva, and therefore pimple. One drop of a 0.2 per cent solution is stated to suppress the corneal reflex for about fifteen minutes.

Agomensin and *Sistomensin* are extracts of the corpus luteum. In 1914 Seitz Wintz and Fingert (*Munch med Woch* 1914, 30 1734) described the isolation from cow corpora lutea of two substances: (1) lipamin or sistomensin found in older corpora lutea. It is claimed that the first of these extracts produces menses in amenorrhoeic women and that the second inhibits the menstrual function. The manufacturers give numerous references to clinical workers who claim to have obtained satisfactory results with these extracts.

British Medical Journal.

RECURRENT DISLOCATION OF THE SHOULDER-JOINT

TRAUMATIC dislocation of the humerus at the shoulder joint is a not uncommon accident, complete recovery in the course of a few weeks is the rule, with a joint just as useful and secure as it was before the accident. But in a certain number of cases, be it from inherent weakness of the joint and its musculature or because of imperfect recovery of the damaged parts, the dislocation recurs on the application of a luxating force less than that which caused the original injury. The classical example, perhaps, is the hunting man who, having once suffered a dislocation, is very apt to bring on a recurrence in throwing up his arm as his horse takes a stiff hedge or fence, but the facility of displacement may be such that it may occur on comparatively slight movement—for instance, on turning over in bed during sleep. To those who do not realize that the muscles around a joint are of far greater importance than the ligaments in maintaining its stability, it must be matter for wonder, not that luxations of the shoulder sometimes occur, but that they do not happen much more often than they do, for the loose capsule and the small and shallow glenoid cavity seem to invite displacement of the head of the humerus, which is, however, prevented by the postural tone of the muscles—a kind of action which was first described by Sherrington, and of which the importance is being more and more appreciated by surgeons.

The weak spot in the defences of the joint is situated at its lower anterior part, where the muscles are less closely placed than elsewhere, and where on extreme and forcible abduction and extension the head of the bone either tears through the capsule or rends it from its attachment to the scapula. This is the movement which is associated with recurrent dislocation in nearly all cases. Many persons engaged in non-laborious occupations may go through the daily routine without over-abducting the arm, and to such a recurrent dislocation may not be of much moment. But to those whose bread has been earned by heavy labour, involving often the freest possible arm movements, such a disability may mean unemployment and privation, and it is likewise a misfortune for the athlete and the sportsman. For such a radical cure is necessary, or at least desirable, and it has been attained by various operations in a number of cases.

These proceedings may be classified as operations (1) on the joint capsule, (2) on the muscles, and (3) on the bones. The last class may be dismissed from our survey, as only applicable to special cases. The first of these has been in great favour in the United States, and has undoubtedly given good results. Dr. T. Turner Thomas of Philadelphia, who has long been a consistent advocate of capsulorrhaphy, read a paper on the subject at the annual session of the American Medical Association last May, an abstract of which has recently been published.¹ Dr. Thomas's name is well known in this connection, and this is by no means his first publication on the subject, which he has studied for a good many years. He now states, as the result of his experience of operations on fifty-seven

shoulders of fifty-four patients, that capsulorrhaphy "offers close to 100 per cent cure of the dislocations, and close to 100 per cent functional results in non-epileptic patients." Epileptics—who, it should be said, are particularly liable to this disability—are often incapable of carrying out after-treatment properly. This claim, which amounts to one of universal success and no failures, is a big one, and we fear that it is not justified by the case histories which Dr. Thomas has published. Possibly he means that he looks forward to such a result in future practice.

He admits two "acknowledged failures" out of thirty-three cases, or 6 per cent, and dislocation has recurred once at least in eight other cases, so that the percentage of undoubted cures is 66. But Dr. Thomas does not admit that one recurrence after proper after-treatment means failure. On the contrary, he holds the original opinion that a rent in a capsule thickened by operation causes fresh inflammation and increased thickening provided that stretching is prevented for a long enough time afterwards. Whatever might be the verdict of the morbid anatomist, the history of some of his cases seems to bear out this assertion. According to Dr. Thomas, then, a shoulder that has once been dislocated, provided that abduction and outward rotation of the arm have been strictly limited for some months, is more secure than an uninjured one. He maintains that in the typical cases of recurrence the head of the bone when luxated lies in a hernial sac of capsule, and thus displacement causes no trauma of capsule and no salutary inflammation and thickening.

Operations on muscles consist of proceedings for shortening the subscapularis, division of the tendon of the pectoralis major, or for slinging up the head of the humerus by a strip of muscle detached at the lower end from the front part of the deltoid and passed through the axilla to be fixed to the deltoid behind the joint. This latter operation was introduced by Clamont and Ehrlich in 1909,² and in the hands of Mr. Ollenschaw of Manchester it has given quite satisfactory results. In his book on orthopaedic surgery, which is noticed on page 907 of this issue, Dr. Warren Sever of Boston, Massachusetts, takes a thoughtful survey of this subject. He holds that although plying or constricting operations on the capsule have been apparently successful in a number of cases, yet that the success was due, not to any contraction of the capsule, but to the necessary interference with the muscles around the joint, and in particular to the division and subsequent suture of the tendon of the subscapularis near its insertion, which is a marked feature of Turner Thomas's operation of capsulorrhaphy. Other operators have divided part of the pectoralis major in order to enlarge the field of inspection. These two proceedings are, Dr. Sever says, the two important factors, and all that are really necessary. There is, we think, very great weight in these arguments, especially as regards the subscapularis tendon.

In considering dislocations we are too prone to forget the injuries which must necessarily be suffered by the muscles. Everyone is familiar with the atrophy of the quadriceps extensor which ensues on fracture of the patella, and with the difficulty of remedying it. Does it not seem probable that a similar atrophy and impairment of postural tone may be present in certain of the shoulder muscles after dislocation of the joint? The consequent disturbance of the balance between different muscles or groups of muscles might well account for the recurrence of dislocation.

PRE-CANCEROUS CONDITIONS

IN view of the limitations of surgical or other forms of treatment in full blown malignant disease much attention has been directed to the conditions which may precede it, since, if these were known and proved amenable to control, more certain and satisfactory results might be expected. Even if these prodromal states produced little in the way of warning signs or symptoms, yet their recognition would advance our knowledge of etiology—still a dark field to the pathologist. Does the malignant condition start *de novo*, or is it the terminal phase of a series of pathological states? Some there are who stoutly maintain the one and others as stoutly the other. It must be confessed that the easily detectable pre-cancerous stages on which all would be agreed are few, but that such do exist admits of no doubt. On the other hand little purpose is to be served by maintaining that in all cases of malignant disease there is a definite preceding lesion.

The discussion held on November 4th in the Surgical Section of the Royal Society of Medicine (reported at page 899) served to emphasize at once the known pre-cancerous conditions, or rather those that are generally recognized as apt to terminate in malignancy, and the mass of dubitable material built on speculation. Dr. Sequeira presented an admirable summary of the pre-cancerous skin conditions: *xeroderma pigmentosum*, *eczema*, *dermatitis*, *tar* and *arsenic* warts, etc., and of *leucoplakia* of the tongue—conditions that lend themselves to direct examination and well authenticated histories. The frequency with which these lesions develop into epithelioma is capable of more or less exact computation, and the opinion is becoming more general that in all cases, if the natural evolution were not interrupted and the patient lived long enough, such a catastrophe would result. That certain forms of treatment may have the effect of increasing rather than diminishing this liability is borne out by the results of x-ray treatment of lupus. Here the proportion of cases developing into epithelioma has been greatly increased by such treatment.

Of recent years the question of the relationship of simple gastric ulcer to malignant ulcer has become prominent, and rather wild statements, unsupported by trustworthy pathological observations, have been made on the point. One of the speakers called attention to the remarkable discrepancy between the earlier and later estimations given by surgeons who have written on this subject. If excisions of the whole or a great part of the stomach for simple ulcer are to be justified (and even in the best hands they are accompanied by a mortality far from negligible), it must be on other grounds than the excessive tendency to become malignant. It is probable that the danger of a simple gastric ulcer becoming malignant is no greater than the operative risk attending gastrectomy for the condition. More definite information of the liability might be obtained—as Mr. Cope suggested in the course of the debate—if the subsequent histories of perforated gastric ulcers could be followed up.

Of the pre-cancerous states in other parts of the intestinal tract little is known. That multiple polyp of the large intestine frequently undergo malignant degeneration is usually admitted, but that carcinoma in that situation are generally accompanied by papilloma, as one speaker maintained, is a proposition to which few pathologists of experience would assent. The most interesting part of the discussion, we should have expected, would have centred round the pre-cancerous conditions of the breast but the con-

tributions of the speakers were not particularly illuminating. Until we have more certain pathological observation, not merely semi-speculative conclusions it is open to doubt whether there is an appreciably higher percentage of cancers developing from chronic mastitis than in mammary glands not so affected previously. That in cancer of the breast there are often widespread changes, as has been demonstrated by Sir Lenthal Cheate, may be accepted, but that such minor changes are pre-cancerous, in the sense that they would invariably or even frequently develop into cancer, is far from being certain.

THE ROYAL SOCIETY

THE annual meeting of the Royal Society will be held, as is the custom, on St. Andrew's Day, November 30th. The usual periods of office having expired, Sir Charles Sherrington will be succeeded as president by Sir Ernest Rutherford, and Sir William B. Hardy as one of the secretaries by Dr. H. H. Dale, head of the department of biochemistry and pharmacology of the Medical Research Council's Institute at Harpenden. Among the other members of the council of the society are Dr. J. B. Jentles, professor of physiology in the University of Sheffield, Professor J. C. G. Ledingham of the Lister Institute, Sir Thomas Lewis, lecturer on cardiac pathology, University College Hospital Medical School, London, and Dr. J. P. Hill, professor of embryology, University College, London. Sir David Prain will continue in office as treasurer of the society.

ERRORS OF VISION AND AVIATION ACCIDENTS

THE importance of visual defects in causing motor-car accidents was indicated in our columns of December 8th, 1906 (p. 1636), and it was pointed out that, besides refraction errors, weakness of muscular tone and defective accommodation were sources of danger. The author of that article, now Wing Commander E. C. Clements, R.A.F.M.S., in an address at the Royal Society of Medicine last Monday, dealt with the visual problems concerned in flying, which were shown to be of a similar nature for efficient flying correct balance of the eye muscles was essential. Before the war he had examined a considerable number of bank clerks, students, typists, and other close workers, and had shown that failure of binocular vision was followed by constitutional disturbance. Investigation of flying accidents had brought out the interesting point that in many cases the aviator concerned had been employed in such occupations as these, which involved continuous strain upon the mechanism of accommodation. In about 70 per cent of all flying accidents some error of judgement in landing had been found to be responsible. It was therefore of the greatest importance to ensure that the visual apparatus of those who intended to fly was healthy in every particular. The tests most employed were the following. Convergence was tested by the ability to focus an object at decreasing distances from the face. If convergence was still possible at a distance of two inches this was classified as "very good", at two to three inches "good", at four inches "fair", and anything over four inches was considered "poor". The errors brought to light were inability to fix at a nearer distance than four inches, and the continuance of convergence in one eye after it had ceased in the other. A second test was the covering of one eye while an object was brought near to the nose. The eye was then uncovered, and should be found directed to the object. The exclusion of conditions of heterophoria was of considerable importance, and the usual test was employed, red glass being placed in front of one eye and green glass in front of the other.

With normal vision two images were obtained, but in abnormal conditions one image was suppressed either temporarily or permanently. This suppression might be the result of habit, and Commander Clements pointed out that in some schools the pupils were taught to close one eye—in reading the slide rule, for example—in order to secure accuracy. This practice tended in time to induce deliberate suppression of one of the two images produced by binocular vision. He attached particular importance to the frequent occurrence and serious consequences of this suppression, and in a series of examinations of engineers' draughtsmen he found it was particularly marked. This type of person invariably failed as an aviator. In the examination of 397 civilian pilots 387 showed no visual errors, 3 were border-line cases, and the remainder showed more serious errors. Of 124 civilian pilots distinguished for their ability to land skilfully, 123 showed the absence of visual errors, whilst the remaining pilot was eventually proved to be suffering from temporary fatigue owing to a long railway journey. The immense importance, therefore, in flying of these visual tests could not be overestimated, since in landing after a flight rapid and accurate changes in accommodation were required. The condition of heterophoria was also of great interest in industry, and, as the result of examining a long series of industrial accidents, he had found that hyperphoria and hypophoria appeared to account for the majority of them. In one factory, for example, where he had examined 53 boys, 43 of them who were without visual errors had an average of 0.8 accident per boy, while the 10 boys with visual errors had an average of 2 accidents per boy. To illustrate the effect of these errors on the earning power he added that in a brush factory out of 17 persons 2 were outside the border-line of visual error, and these two earned 25 per cent less than the remainder. He discussed the ability to judge distance as it developed from infancy, this ability was first based on monocular vision, then on binocular, and finally on the formation of tracts of association and on co-ordination. He had been able to test the power of orientation in space possessed by a patient suffering from a temporary paralysis of the sixth nerve on one side. Using body movements, this patient was able to localize an object correctly, but without this aid and relying only on ocular movements there was considerable error. It was further pointed out that the part played by heterophoria in the production of neurasthenia was very considerable, but was receiving inadequate attention from medical practitioners. He had found also that after such conditions as concussion, neurasthenia, influenza, and the fatigue brought on by high altitudes, there might often follow loss of convergence and binocular vision. There was a considerable amount of evidence to show that this loss was toxic in origin. Convergence errors due to influenza disappeared slowly, but there was some tendency to the formation of a habit of suppressing one image. The occurrence of fatigue tended to increase suppression of one visual image, and flying accidents were due not so much to failure of visual acuity as to failure of convergence, whether arising from fatigue, toxic conditions, or essential causes.

PREVENTION OF THE COMMON COLD

The chief subject discussed by the Medical Officers of Schools Association at its meeting on November 6th (reported this week at page 901) was the prophylaxis of common colds in schools by means of preventive inoculation with a vaccine. A boarding-school provides an excellent place in which to assess the value of this form of treatment, because those who have been vaccinated can be watched for some time, and because external conditions which affect such a comparatively isolated population can usually be recorded. There have been instances in which vaccination

against coryza has been conducted with the rigorous control demanded of a scientific experiment, but these have not been on a large enough scale nor led to sufficiently unequivocal results to convince the sceptical. Many of the experienced school medical officers who took part in last week's discussion obviously have faith in prophylactic vaccination against colds, and some could point to successful mass inoculations. When, however, the lack of precise knowledge about dose, optimum time of inoculation, repetition of doses, and duration of immunity after antiserum vaccines is compared with the well founded knowledge about other forms of vaccination—as, for instance, against typhoid fever—we realize that hesitancy and lack of confidence are not out of place. Nor should it be forgotten that no single *causa causans* of the group of infectious loosely labelled as coryza has as yet been identified. With so many uncertain factors it is not surprising that opinions differ, and the meeting did wisely, we think, in recommending the council of the association to set up a subcommittee to investigate the best methods of preventing infectious catarrhs in schools. The subcommittee will perform an important public service if it collects and reviews the literature of previous attempts in this direction, and after sifting the evidence draws up a workable plan for putting vaccination against colds to the test on a large scale. The uncertainty which exists about this more technical method of prevention naturally resulted in greater prominence being given to vaccination than to other and better established means of prophylaxis. But such important measures as nasal and nasal hygiene, avoidance of overexertion, and attention to proper ventilation and clothing, must not be relegated to a subordinate position. These are well tried common sense precautions, and it would be a pity if hopes based on the possible value of a few thousand million microbes in a bottle should induce any school medical officer to neglect rational measures which have proved their worth.

EMPHYSEMA AND BRONCHIAL CATARRH

For many years Dr. Emile Feuille of Paris has been investigating the etiology of bronchial catarrh and associated conditions. Some seventeen years ago he reported that he had been able to produce these conditions experimentally without the intervention of a primary bronchial lesion, and suggested that leucocytic stases and migrations played an important part in the pathogenesis. In 1922, while studying anaphylaxis in the dog, he obtained precisely similar bronchial conditions after subcutaneous and intravenous injections of toxic substances, and he was able also to confirm his previous view that mercury was a most effective treatment for them. He has now given an account of the changes found in the lungs of certain animals after excessive haemorrhage, or after injection of emulsions, chromic acid, egg albumen, horse serum, and antidiphtherial serum. With the first two poisons pathological changes appeared in the lungs in a few minutes, with the remainder after several hours. Twenty-four hours later the following conditions were found. The bases of the lungs were collapsed although an overexcess floated in water, and the bronchial vessels were dilated, the bronchial epithelium was invaded and loosened by lymphocytes which, mixed with red cells and epithelial debris filled the bronchial lumen. No evidence of any primary bronchial irritation was discovered. The lungs were intensely congested, with some infarcts surrounding cavities, scarcely any normal lung tissue was to be seen. A preponderance of lymphocytes, sometimes massed together, was noticeable. The elastic fibres of the lung were broken. The macroscopical appearance was that of ordinary small lung emphysema with isolated patches of

infiltration on the bronchial walls. In animals kept alive sclerosis began to appear in five or six days. The patches of lymphocyte infiltration became transformed into fibrous plaques, but there was still no evidence of local irritation. This pathological process the author wishes to distinguish as a sclerosis of morbid leucocytic origin, for which no pre-existent local lesion is responsible. Similar leucopathic scleroses appeared freely in the kidney and liver. If the dose of the toxic agent was large definite atrophic emphysema followed from rapid and extensive destruction of tissue, sclerosis only followed very small doses, after each such injection the sclerotic area extended. Such pulmonary changes were found to persist as long as three to four months. The blood vessels dilated simultaneously, and repeated weak injections of the poison caused an extensive infiltrative endarteritis like that in anaphylactic shock. In anaphylactic shock just below the fatal degree, in dogs sensitized to antiphragmin serum, to horse serum, or to egg albumen, subacute pulmonary emphysema followed in less than an hour, with rupture of the pulmonary elastic fibres and intense vaso-dilatation. The similarity of the pulmonary changes in anaphylaxis and in these toxic conditions, and the resemblance of the anatomico-pathological pictures in the two conditions suggest to Fennell that anaphylaxis is the outcome of the activity of a toxin resulting from a dyscrasic condition, with a secondary factor acting on the nervous system to produce vaso-dilatation. These pulmonary changes caused by anaphylaxis or toxic poisons, and characterized by the absence of any primary bronchial lesion, i.e., he thinks, entitled to be placed in a special category, and he proposes to apply to them the term "pneumoses" or "bronchopneumoses." Without rejecting accepted theories of the causation of emphysema, he holds that his dyscrasic or general toxicemic theory explains certain pulmonary conditions, the local changes are secondary to a general toxicemic or anaphylactic condition, for "an antigen can evoke the lesions of anaphylactic shock, the ultimate consequences are the same, usually atrophic sclerotic emphysema." Secondary infections occur and maintain a general toxicemia, chill may act in the same way. He suggests that a small, sharply defined, and closed tuberculous focus in a lung may give rise to such a dyscrasic state, from this such non-tuberculous conditions as asthma, pulmonary congestion, and general atrophic emphysema may ensue, either from the setting free of toxins or the absorption of products of cell destruction. He recommends that in asthma or early bronchopneumonia subcutaneous injections of colloidal silver should be given on alternate days, with daily intramuscular injections of mercury for a fortnight. Thyroid and adrenaline extracts may be given by the mouth, together with enough calomel to maintain slight diarrhoea. A similar but milder course of treatment is suggested for chronic bronchitis and emphysema.

MEASURING THE FRUITS OF HYGIENE

A COMMISSION appointed lately to inquire into certain matters affecting the health of estates in Malaya prints as an appendix to its report a statement submitted as evidence of the value of money spent on health measures. Obviously such outlay is economically productive in the fullest sense of the term, but there is perhaps some danger in an attempt to prove this by the device employed of contrasting one period with another in tabular form. Without the detailed information necessary to elucidate this particular statement we therefore abstain from comment, allowing the facts thus reported to speak for themselves. The product under cultivation on the estate making the return is presumably rubber. From the commission's

report it is clear that the medical and sanitary provision to be made on each estate is determined almost entirely by the policy adopted by the management, the execution of that policy being committed to a visiting medical practitioner, who, within the limits prescribed for him, is made responsible on a contract basis for the health of the labourers. It should be added that, while the commission included two medical practitioners, its personnel was predominantly lay. The purpose of the appendix is, as we have indicated, to contrast the value of expenditure on hygiene (a) when the measures were crude and the main effort was directed to curing the infected coolies, and (b) when health measures were understood and the main effort was directed to the prevention of disease. For the purpose of (a) the year 1911 is taken, and for (b) 1923. Conditions, it is admitted, have greatly changed in thirteen years, and the comparison can only be general, but "there is sufficient to show that money spent properly in the prevention of disease is sound business." The estate from which the figures (reproduced below) are taken was, and is potentially, as unhealthy as any estate in the Federated Malay States. It was first opened in 1906.

	1911	1923
Average cultivated	1 632 acres	2 600 acres
Average labour force	870 Indians only*	450 (all labour)
Dependants	1 practically nil due to deaths	220
FOB cost	\$1 03	18 64 cents
Yield	83 000 lb	778 000 lb
Total expenditure	\$240 215.33	\$145 018.44
Medical (cure)	\$12 444	\$6 208.67
Medical (prevention)	Nil	\$9 531.20
Death rate	232 per mille	3 per mille
Number of deaths	202	2
Staff (Europeans)	7	4
Hospital	Overflowing	Empty
Total loss of labour	862	13
Percentage loss of labour	100	30
Cheek roll average	30 (15% above standard)	35.5 (standard)
Hospital admissions for year	1 084	275

* There was also a large but unknown number of Chinese.

This tabular contrast is supplemented by some additional particulars intended to throw further light on the changed conditions. The staff in 1911 consisted of "seven unhealthy Europeans, all stating they could never marry, constantly very sick, cheering themselves with the bottle, taking no interest in bungalows or gardens." In 1923 it consisted of "four healthy Europeans (three married, one engaged), three healthy children, pretty gardens, comfortable bungalows and no drinking, no one is ever away on sick leave." In 1911 the labouring population of the estate consisted of "870 coolies, with practically no dependents, miserable cowering wretches with narrow shoulders, prominent stomachs, bloodless, lifeless, miserable squab in the lines, no gardens or livestock, and no children born alive." In 1923 there were "450 coolies doing three times the work done in 1911, 220 healthy old people and young children, births have become a chronic habit, the coolies are happy, fat, well set-up people, clean and well clothed, there are excellent gardens, over 60 head of cattle, the property of the coolies, hundreds of goats, and thousands of chickens." In regard to organization and efficiency, it is said that in 1911 the tappers were sent out to new tasks every day, one-third to one-half of the tasks had to be tapped or finished in the evening as the coolies had returned sick or too weak to finish the work. "Now a coolie is not taken off his task for months on end, and

* Report of the Commission appointed to inquire into certain matters affecting the health of estates in the Federated Malay States, 1924.

men has to finish off tasks in the evening. Other works were of course in the same condition. In 1911 a gang was sent out digging graves every day and we never got third of our requirements. Coolies constantly died in the field. It can well be imagined that in 1911 there was very little organization, efficiency, or decent work done. The estate is now one of the cheapest producers in the Federated Malay States, and the cost of production compares favourably with Ceylon and Java."

NEW YORK ACADEMY OF MEDICINE

THE New York Academy of Medicine was founded eighty-two years ago for the purpose of advancing the science and art of medicine, maintaining a public medical library, and promoting public health. Last year the Carnegie Corporation undertook to provide a new and larger building for the Academy, and the Trustees of the Rockefeller Foundation offered in endowment, these two gifts amounting together to upwards of £500,000. The foundation stone of the new building was laid on October 30th. In an editorial article announcing this ceremony the *Journal of the American Medical Association* has given an appreciative outline of the work, past and present, of the Academy, and of the steps taken by its executive to ensure that none of its activities, now about to be increased, shall overlap those of the American Medical Association and its councils on education and on pharmacy, or of the Association of American Medical Colleges. The munificent gifts of the Carnegie Corporation and Rockefeller Foundation have made possible six requisitions: a full time director, an executive librarian, a new library service, a bureau of clinical information, a committee for post-graduate medical education, and a monthly bulletin. The post of executive librarian, we learn from our Montreal correspondent, has been filled by the appointment of Dr. Archibald Millock, M.R.C.P. Lond., assistant physician to the Royal Victoria Hospital, Montreal, who will take up his new duties at the beginning of next year.

THE PHYSIOLOGY DEPARTMENT AT KING'S COLLEGE

THE extensions to the department of physiology at King's College, London, have now been completed, and were formally opened on November 6th by Professor W. D. Halliburton, F.R.S., Emeritus Professor of Physiology in the University of London. A reception was given in the new laboratories at which were present many well known physiologists and biologists. The new building will provide facilities for experimental research, for the teaching of advanced practical mammalian physiology, and a professor's room. Further, the rooms formerly occupied by the bacteriology department have been taken over for biochemistry, for the provision of animal and polarimeter rooms, and for a staff room and library. The reception was followed by a public inaugural lecture, entitled "Science and culture," by Mr Julian Huxley, M.A., who has recently been appointed to the chair of zoology at King's College in succession to the late Professor Arthur Dendy, F.R.S.

FOCAL INFECTION

At the James Mackenzie Institute for Clinical Research, St. Andrews, on November 3rd, Professor Lorain Smith discussed the pathology of focal infection, illustrating his remarks by numerous lantern slides. He demonstrated the spread of infection from focus to focus in many infective conditions including tubercle and showed clearly that certain organisms could circulate in the blood without giving rise to noticeable symptoms until they formed a focus in the tissues. These foci were found in connexion with the lymph nodes which were exceedingly numerous in all tissues. On the settlement of an organism the local resist-

ance might be sufficient to destroy it, but if the focus became established it acted as a centre of distribution and other foci were established. The main agent in the destruction of organisms was, however, undoubtedly the blood. The explanation commonly given of the formation of foci was the arrest of active material by mechanical obstruction in lymphatics or capillaries, but similar focal lesions resulted from the presence of soluble toxins in the blood. An investigation into the focal mechanism responsible for such results should advance greatly our knowledge of the liability to disease. Professor Lorain Smith drew attention also to facts observed by Rosenow, suggesting that infective organisms might sometimes require a selective preference for certain sites. Typhoid bacilli, for example, showed a noteworthy preference for the gall bladder, while metastatic infection in bronchiectasis tended to appear in the central nervous system. In conclusion, he said that while the problem of general immunity had been widely investigated, the question of local immunity and the focal mechanism upon which it was dependent had not been worked out. The paper gave rise to an interesting discussion.

THE MEDICAL PROFESSION AND THE OFFICERS' TRAINING CORPS

OUR allusion a few weeks ago to that well known regiment of the Territorial Army, the Artists Rifles, brings to mind the existence of the intimate connexion between the medical profession and the Officers' Training Corps. The Senior Division of the O.T.C. is established at most of the universities in Great Britain, the larger ones possessing, in addition to other units, flourishing medical units. The object of the O.T.C., as stated in the War Office Regulations, is to provide students at (schools and) universities with a standardized measure of elementary military training, with a view to their applying eventually for commissions in the Militia, Territorial Army, or Regular Army Reserve of Officers (including the Supplementary Reserve). The medical students at the various hospitals form the only field for recruiting for the medical units of the O.T.C. Such highly technical qualifications as these of the medical profession are to a great extent wasted if these students would be required, in a national emergency, as medical officers in the army, and those possessing an O.T.C. training would be eligible for commissions without additional military training. The military authorities, we are informed, have taken steps to prevent a recurrence of the conditions in 1914, when hundreds of the flower of the nation's youth died fighting in the ranks instead of being retained for training as officers. In London the University possesses a flourishing and highly efficient medical unit in which all the leading hospitals are represented.

It has been decided to create a Lothian Scholarship and a Duling Prize for the encouragement of malacological study in memory of Dr Norman V. C. Lothian and Dr Samuel Darling, the British and American members respectively of the Malaria Commission of the League of Nations, who were killed on May 21st last in a motor accident near Beirut while investigating malaria conditions in Syria. The "Lothian Scholarship," for which a credit has been found in the budget of the Health Organization of the League, will be awarded by the Malaria Commission to a selected candidate, whose course of study should be in conformity with the general programme of the Commission. The Duling Prize, in the form of a medal or other reward, will be given to the scientist who has carried out recent distinguished research work on a subject connected with malaria which comes within the scope of the Commission's investigations. It is proposed to raise the funds for the latter foundation by private subscriptions.

CHRONIC NASAL FOCAL SEPSIS

THE SIMON LECTURE

THE SIMON LECTURE of the University of London was delivered in the Baines Hall of the Royal Society of Medicine, on November 5th, by Dr P. WATSON WILLIAMS of Bristol, with Sir WILLIAM MILLICAN in the chair. Dr Watson-Williams took as his subject "The toll of chronic nasal focal sepsis on body and mind," in the firm belief, he said, that the specialty of rhinology was destined to afford valuable assistance in the solution of some of the problems arising in the domain of the physician, surgeon, and chemist. More and more clearly it was being recognized that focal sepsis was directly accountable for disease far afield from the local infective source. Sepsis had also an important bearing on many cases of mental disturbance, and even of delusional insanity. The lecturer excluded from the discussion oral and tonsil sepsis, apart from "adenoids," as being already appreciated, and sometimes even overestimated perhaps, obscuring the factor of sinus sepsis. Septic tonsils and adenoids were often only sub-infections of nasal sinus infection, and hence came those cases of repeated removal of adenoids reinfected by an overlooked sinus infection. The complications of nasal focal sepsis, apart from direct extension to surrounding structures, involved other territories in two distinct ways: (1) by the infective organisms being inhaled or swallowed and thus directly entering the pulmonary or the gastrointestinal tract, and (2) by the toxins (and sometimes the organisms themselves) passing into the lymph vascular or blood streams, and thus involving the liver, arteries, kidneys, joints, peripheral nerves, and the cerebral hemispheres.

Infective Organisms Inhaled or Swallowed

It was well known that septic tonsils and adenoids were a fruitful source of recurrent bronchitis in children, but the septic focus might lie in a nasal sinus, particularly in later life, when the tonsils and adenoids were normally atrophied. Again, while it was generally recognized that enlarged cervical glands were much more often due to sepsis than to tuberculosis, it had yet to be determined how great a percentage of so-called pulmonary phthisis, cases unsupported by the evidence of tubercle bacilli, were in reality non-tuberculous and simply subinfective pulmonary sepsis. A nasal sinus infection was a serious factor in pulmonary tuberculosis, but the wasting of chronic sinus sepsis, with bronchial subinfection, nocturnal rise of temperature, night sweats, expectoration, and febrile reaction to exercise, afforded a clinical picture hardly distinguishable from true pulmonary tuberculosis, often aggravated by a chronic septic laryngitis.

Patients with septic infection of the mouth, throat, or nose often swallowed daily millions of pyogenic organisms with relative impunity, the gastric juice being strongly bactericidal. But, when overwhelmed with the swarms of virulent organisms from the mouth or nose, gastro-intestinal catarrh and flaccid dyspepsia quite commonly developed, and diarrhoea, alternating with constipation, and even definite colitis, were not rare consequences. How far appendicitis and gastric or gastro-duodenal ulcers were caused by persistent infection from organisms swallowed it was difficult to determine, but the extraordinary percentage of patients with chronic sinus infection who had undergone the operation of appendicectomy, or had suffered from gastric or duodenal ulcer, was most striking and suggestive. The coincidence was usually unnoticed, because in that connexion the surgeon and the laryngologist respectively did not usually make the necessary inquiries. The infectivity of chronic nasal sepsis and its causal relationship to appendicitis was perhaps even more strikingly suggested in families where a parent acted as a carrier infecting the children, and Dr Watson-Williams cited two illustrative examples of this. It was recognized that diphtheria, scarlet fever, and enteric fever might be spread by "carriers" but in Dr Watson-Williams's opinion the spread of chronic septic throat and nasal infection was a still more constant menace.

Lymph-vascular or Blood Infection

Seriation and various manifestations of neuritis were the common heritage of focal sepsis. While migraine, supra-orbital and occipital headache were now commonly ascribed to nasal sinusitis, it was less generally recognized that the intense neuralgic pain in the fifth nerve, of the double-nerve type, might be due to a toxic neuritis from pyramidal sepsis. Various affections might arise from irritation of the sensory nerve endings in the mucosa, either directly or reflexly through communications of the sensory nucleus of the fifth nerve with the motor vagus nucleus in the medulla, such were neuralgia, paroxysmal sneezing and asthma of nasal origin. The influence of a nasal stimulus on the vagus was recognized in practice when smelling salts were used in faintness. Many infectious involving the orbit and globe were often legacies of nasal sinus sepsis, but, being direct extensions of septic infection from the nose, were outside the scope of the lecture. Iritis and ecchyma were always septic in origin, and the recorded examples of exophthalmic optic neuritis, relative scotomata and enlargement of the blind spot, were very numerous and important. Rheumatism and rheumatoid arthritis afforded plentiful examples of either subinfection or toxemia from nasal sinus sepsis, although, hitherto, investigation of the source of infection had been mainly directed to the teeth and tonsils. Often the last areas to be considered were the nasal sinuses and the ear.

In Dr Watson-Williams's own experience a number of cases of rheumatoid arthritis had been cured or relieved by draining infected nasal sinuses.

Relation of Local Sepsis to Mind and Character

It was, the lecturer said, common knowledge that toxemia from oro-nasal sepsis, in the form of septic tonsils and adenoids or dental sepsis, might cause neurasthenia or mental unsoundness, but it was only recently realized that the degree of sepsis, not the hypertrophy causing mechanical nasal obstruction, was the measurement of the mischief caused by the tonsils and adenoids. Key and Retzius, and later Andre, among others, demonstrated the close relation of the lymphatics of the pituitary membrane crossing the cribriform plate to the perimeningeal lymph spaces. Even if there were no direct communications between them they afforded channels for cerebral intoxication, by a process of transudation, much as paralytic tetanus infection caused a serious perilabyrinthitis. This might in a measure explain the frequent association of nasal sepsis with disturbances of mind and character, and also the frequent improvement in the mental outlook, as a result of operative removal of some source of sepsis in the teeth, tonsils, and adenoids, or in chronically infected sinuses. With the added social responsibilities and relationships of adult life, the psychic disturbances from focal sepsis were more striking and often more disastrous, the slightest degrees of mental disturbance which, in a child, might be hardly noticed in the adult might be sufficient to cause unhappiness to the patient and those about him. Again, on account of the mild toxemia, the mental deterioration might be so very slow as to be attributed to alteration in character rather than to a form of disease. The retro individual often became disinclined for exercise, actual muscular weakness, being added to lessened zest in life. When such symptoms were not recounted for by a recent illness, such as influenza, the patient was apt to be labelled neurasthenic and treated by rest, a voyage, and so forth. Improvement often followed such measures, but, if an unsuspected focal sepsis was the essential cause, the symptoms probably recurred in course of time, and might become more pronounced. The depression might deepen into profound apathy or melancholia, suicidal impulses were by no means rare, while the patient certainly might drift into habits of intemperance, and loss of mental balance might end in definite hallucinations or delusional insanity.

Crime and Sepsis

There were two directions in which the infective disease might operate. The first was by mental confusion and loss of memory, and of this a good illustration was afforded

by a lady who had frontal sinusitis and stole a ring from a friend's dressing-table. The patient never knew that the matter had been in the hands of the police, and later told Dr. Watson-Williams as news all that had occurred, evidently ignorant of everything save her loss of memory. He had no doubt whatever that other instances, such as failure to account for money received, had occurred quite innocently, the patient suffering from "aprosia" due to septic toxæmia. In the second class, with delusions of suspicion, or of being persecuted, or poisoned, the unbalanced mind was liable to lead to disastrous crime. Creosote and foul taste of food from sinusitis, both common complaints in such cases, might, in the mind unhinged by focal sepsis, become delusions suggesting "gassing" or "food poisoning." Sir George Savage had recorded examples of the growth of delusion in this way. Dr. Watson-Williams suggested that they were warranted in believing that between these extremes mental depression and confusion might certainly suffice to account for criminal acts which were obviously stupid and utterly at variance with the known character of the perpetrator. Though it might be difficult at present, and perhaps dangerous, to distinguish between those cases in which crime was determined by infections, and those due to innate moral obliquity, it was surely a duty to consider how far sepsis should be ranged with other toxic causes of mental and moral degeneration, such as alcohol, morphine, cocaine, or syphilis, and thus perhaps help to prevent many social and legal transgressions. Ford Robertson's eschewes had furnished evidence of the causal factor of bacterial infection in dementia præcox.

The slightest disturbances of the character, disposition, and power of concentration were fruitful causes of unhappiness in the home, of broken hearts, of business losses, and loss of time and energy to the working man. More pronounced manifestations were seen in the lunatic asylums, perchance in the prisoner or the suicide, amounting to a stupendous toll of truly national import, and the pity of it was that the causal infection was so largely an enable to successful elimination.

On the laryngologists and rhinologists who guarded the portals where such a large preponderance of these infections gained entry lay perhaps a greater responsibility than fell to any other department of medicine and surgery. Every industrial school, Borstal institution, prison, and asylum called for a more systematic co-operation of the rural, laryngeal, and dental surgeon. Of the thousands of suicides that occurred, the story was not unusual that the wretched individual had "suffered lately from pains in the head and was depressed," but the verdict of "Suicide while of unsound mind" closed the chapter without any systematic *post-mortem* investigation to determine the material and remediable cause of those tragedies which, in a very large proportion, was almost certainly some form of toxæmia. In the young delinquent, at any rate, there was reason to believe that the evil genius was much more often "Sepsis" than "Sin."

THE PLACE OF THE MIDWIFE IN THE MATERNITY SERVICE

CONFERENCE IN LONDON

A CONFERENCE arranged by the Post-Certificate School for Midwives, and presided over by Sir FRANCIS CHAMBERS, Bt., M.D., Chairman of the Central Midwives Board, was held in London at the house of the Royal Society of Arts on November 9th, to consider how the midwife can help in the reduction of maternal and infantile mortality.

Dr. J. S. FAIRBAIRN, in an opening paper, urged that there need be no rivalry between the general practitioner and the midwife. Their functions were not competitive but complementary. The sphere of the midwife was attendance on normal labour, and that of the practitioner was the general supervision of ante-natal and post-natal conditions and attendance on difficult labour. The position was complicated by the large amount of midwifery done by practitioners for inadequate fees and, owing to the pressure of other work, often in a hurried manner. One consequence was the high proportion of forceps deliveries in

private practice. The proportion of forceps deliveries in some lying-in hospitals was 4 per cent, in private practice it must be nearer 40 per cent. He did not blame the practitioner, it was part of the system, but forceps delivery was not physiological delivery—which ought to be the primary objective—and with all instrumental interference the morbidity rate went up. He also urged the importance of attracting the best type of women into midwifery practice by the provision of a pension scheme on civil service lines and by a sympathetic attitude on the part of local authorities.

Miss E. M. DETLEFSEN spoke of the value of the midwife in educating both the prospective parents owing to her free access to the home during pregnancy. Rather more than half the births in this country were attended solely by midwives, and in the remainder a midwife ought to be the maternity nurse. The midwife should encourage medical examinations during pregnancy, the first at about the third month. At present the facilities for such examinations were inadequate but from an experience in Middlesex there was some hope that consultative centres staffed by specialists might be set up in the near future.

Dr. F. C. TREMAYNE, M.P., dealt with the role of the midwife in rural areas. He had had something to do, as *medical officer of health*, with bringing the *Midwives Act* into operation in one county, and he remembered looking at the records compiled by one exceptionally charming type of the home-side village midwife who, under the column headed "Presentations," had written "one umbrella!" Village problems were in many respects peculiar. As a rule the rural midwife could not be in independent practice, there were not sufficient births for her to attend. The only way to ensure a proper service of midwifery in the rural areas was to link up this work with all the district nursing services, including tuberculosis and school nursing, and health visiting. The village nurse was as essential as the village parson, and it would be a splendid bit of philanthropy to endow a house in each village for the occupation of the nurse in the same way as ancient piety had endowed the church and rectory.

Sir JOHN ROBERTSON (M.O.H. Birmingham), in a paper read in his absence, said that the town midwife had considerable advantages as compared with her village sister. She went about her duties with the knowledge that if anything untoward happened she could get help at once. The area of her practice seldom extended more than a mile from her door, she could choose her patients, and she need not take any work other than midwifery. The fear was expressed by midwives that they were liable to lose their patients if they sent them to doctors or hospitals. He thought that medical men should practise towards the midwife the same scrupulous etiquette as they practised towards one another. He considered that confinements in hospitals or maternity homes were safer than those which took place in the homes of the people.

Miss LIDDIARD, matron of the Mothercraft Training School at Highgate, said that until some definite arrangements for the better remuneration of midwives and the provision for their future were made, the disinclination of nurses to take up this form of work would continue. She felt that confinement in the home was preferable to confinement in hospital. Child-bearing was a natural thing, why make it unnatural by taking the mother away from her husband and family at such a time? To do so was very likely to add to the shock and trouble of labour.

Miss ROSALIND PAGER, formerly a member of the Central Midwives Board, gave some figures obtained from the Queen's Nurses relating to the work of over 2,000 trained midwives in 1924. The maternal mortality in the cases attended by these women was 15 per 1,000, this figure including all deaths in childbirth from influenza or other causes, not puerperal sepsis alone. This was said to be the unadmissible minimum, but she could not agree. She urged that before a death certificate was given in the case of a woman dying during childbirth a *post-mortem* examination should be made. It would also help matters if the Ministry of Health would issue a notification of birth card uniform for the whole country, with a space for the name of the person who actually delivered the woman.

Miss OLIVE HAYDON, speaking as a member of the Central Midwives Board, said that she had been struck by the number of penal cases in which it was shown that the midwives were incapable of taking the pulse and the temperature. After twenty-three years of the Midwives Act there ought not to be a single midwife on the roll who could not make such records accurately. She believed that the midwives now on the roll were effective in reducing maternal and infantile mortality, but still more could be done if midwives had post-certificate education, which she desired to see compulsory.

Dr FUSTICE HILL (M O H Durham) said that co-operation between doctor and midwife was important but difficult to achieve. In the congested industrial district from which he came the proportion of cases attended by midwives a few years ago was only 19 per cent., thanks to co-operation of the county council and the county nurses association it had now risen to 30 per cent. One of the difficulties had been the strong opposition of the average medical practitioner to the midwife working in his district. Midwives did not get the support from practitioners that they ought to have, and in many cases their welcome was so lukewarm that they were not able to get a living. The position was much the same in Northumberland, where the doctors in many districts were hostile to the midwife, and were content to go on giving a general supervision and leaving the rest to handymen, which in many cases led to disaster. The two main causes of mortality were ignorance and the indiscriminate use of the forceps. As to ante-natal precautions, Miss Doubleday had urged that there should be a medical examination in the third month, but the Durham mother richly thought of calling in anybody until the last month. The midwife was essential for healthy and satisfactory midwifery. He would like to see a limit to the number of cases which a trained midwife could take in a year. He knew instances in which one woman had had something like 300 cases in a year, while other women in the locality could not get a sufficient number.

Dr ANNIE MCCALL thought that in the past the midwife had been in the habit of calling in the doctor a great deal too early. This speaker wanted midwives to be entrusted with the use of a certain number of drugs.

Dr H SCURFIELD said that very little ante-natal or preventive work was being done to-day by medical men, for the reason that there were not enough doctors who had given attention to the matter. The midwife could act as a scout for the obstetrician, but she could not herself do the preventive work. He hoped that something might be done in this country along the lines of an American experiment, whereby the doctors in a town gave up midwifery work altogether, and the work was placed in the hands of midwives, backed by a panel of skilled obstetricians. Most of the present high mortality was due to meddling midwives.

Sir EVEN MACLEAN said that he was prepared, as chairman of the committee of the British Medical Association entrusted with this subject, to explore the problems put forward that evening. The references to the general practitioner—who was a very important person—had been on the whole kind and fair, but some remarks which might be construed as inimical to the practitioner were due to a little lack of understanding. After all, it was the people themselves who chose, they could not be compelled to have a midwife in preference to a doctor, or the reverse, and in the long run they would judge by results. He described the system in Cardiff, where, thanks to the co-operation of all concerned, something near to the ideal arrangement had been worked out. The Cardiff authorities had established a number of ante-natal centres, from these any cases requiring special consideration were sent to a central clinic working in close association with the hospital and medical school, and the clinic had the entire use of thirty-one beds.

Sir FRANCIS CHAMBERS, in closing the discussion, said that he felt strongly that not all cases ought to go into hospital for confinement, but the corollary was that the homes of the people must be such as made confinement safe. The question had been asked in whose practice the mortality occurred. He had for many years, in season and out of season, urged upon the Local Government Board, and afterwards the Ministry of Health, the need for stating on each

certificate who actually delivered the woman, and he would continue to press this point. The Central Midwives Board had been trying to get the local supervising authorities to pay a great deal more attention to the accuracy of taking the midwives of temperatures and pulse readings. The resentment of medical practitioners at the employment of midwives had been referred to. When the Midwives Act first came in, or was first contemplated, there was a great outcry that the bread was being taken out of the mouths of general medical practitioners, and that a set of unqualified practitioners was being raised up, and because he himself signed the diplomas of the London Obstetrical Society he was threatened with proceedings before the General Medical Council. Then came a time when practitioners did not want midwifery work at all and said that it did not pay them, and now apparently, in some parts of the country, they wanted it again. Dr McCull had accused the Central Midwives Board, by implication, of discouraging the use of drugs by midwives. The Board had often been urged to say that no midwife should use any drug except a simple aperient, but that the doctor should be called in. He felt strongly that to deny the use of proper sedative drugs, of which opium was far and away the best, was an act of cruelty. Opium was a combined drug, and contained a great many more things than morphine, and sometimes it had a very useful stimulating as well as a sedative effect. Over and over again in protracted labours he had given it with great advantage. He appealed to everybody not to give up opium, and he had never known any woman in childbirth the worse for a good dose. One point which had to be remembered, in view of the competition for cases between medical students and midwives, was that if midwives attended all the cases the future medical practitioner would not get the experience necessary to qualify them to act in difficult labours. But a number of cases were undoubtedly wasted on women who took a midwifery course with no intention of becoming midwives, but who desired to be health visitors or something of that kind.

Scotland.

RECTORIAL ADDRESS AT EDINBURGH

THE PRIME MINISTER delivered his rectorial address to the students of Edinburgh University on November 6th. The address was delivered in the McLellan Hall, and the Chancellor, the Earl of Balfour, presided.

The Lord Rector said that Sir James Mackintosh had declared a hundred years ago that it was not easy to conceive a university where industry was more general, where learning was more fashionable, and where indolence and ignorance were more disreputable than they were at Edinburgh in his day. A university could only work within the limits of the human material it received from the homes and schools of the country, but it was a rich storehouse of knowledge, and an instrument for increasing knowledge, for some students—a small proportion—did continue to add to the accumulated learning of the ages. Besides this a university must be regarded as a school of character. An ideal character was a harmony of many virtues, and it was a tradition to give to truthfulness the position of the cardinal virtue. The inculcation of the practice of truthfulness, no less than the acquisition of knowledge, was the motive force of the educational system. The student was there to learn habits of accuracy in measurement, precision in statement, honesty in handling evidence, and fairness in presenting a case. That was the goal of British education, because it was recognised that no man could be a worthy citizen whose word could not be trusted, and whose deed was compounded of deceit. Mr Baldwin recalled a passage in which John Locke showed himself so impressed with the defects of language as to affirm that if anyone "shall well consider the errors and obscurity, the mistakes, and confusion that are spread in the world by an ill-use of words, he will find some reason to doubt whether language, as it has been employed, has contributed more to the improvement or hindrance of knowledge among mankind." It was possible at all events

to agree with Bentham that "error is never so difficult to be destroyed as when it has its roots in language." No small part of education lay, therefore, in learning the right use of words, in tracing their birth and behaviour, and in fitting them closely to facts and ideas. No man who could do good Greek or Latin prose could deceive people with words unless he sinned against the light, and he could no longer be deceived himself. Through mathematics was to be learned on the threshold the very lesson which, universally known and applied, would prevent daily mistakes which might be disastrous. The principle that two and two made four, and could, in no circumstances, make anything else, was a principle taught through all the physical sciences. Efforts should be directed to compelling the material facts of the world to reveal their nature and to watch their behaviour; truth was the accurate statement of the facts observed. Lastly, there was the study of the ultimate sciences, the science of sciences, moral philosophy, for which the University of Edinburgh had been justly famous. There had been a time when it might be said that the chief export of Scotland was metaphysics. Philosophy forced the student to examine the assumptions on which all the other sciences rested and the hypotheses by which they all worked. Magic, myth, ritual, religion, the mysterious and emotional story of human belief, the theological speculations of mankind, the very instrument by which mankind knew anything at all, were all so examined as facts of experience, and an attempt was made to interpret them and fit them into some coherent explanation of life and destiny. Throughout all these activities there was a double motive of acquiring knowledge and of learning to think truly, and the latter was the more important task. Why was it, he asked, that in politics a lower standard of habitual truthfulness was alleged to prevail than in the world of science or of business? He thought that primarily this was due to the fact that ever since states began they had been in peril of war, and the preparation for war. They had had recourse to the stratagems of diplomacy and the dropping of the ordinary code of morals. The statesman's goal had been the preservation of the State, and reasons of state had been held to justify all policies. Grotius had declared that human life was essentially a society, and that fidelity to pledged word was its most important law. On the other hand, the principles of Machiavelli had been accepted in Europe, at any rate as late as the days of Cavour and Bismarck. It had been the prevailing view for centuries, openly avowed and defended, that there could be one code of morals among nations and another more exacting code among individuals, but this view had never in this country been accepted in the bold and summary form in which he had put it. The party system had its advantages in team work and loyalty. It appeared to our sporting countrymen as a game with rules which were, for the most part, honourably obeyed. But the party system put a certain embargo on complete frankness of speech in the arena of debate. The material of politics was human nature, with motives honourable and base, appetites for power and for service, memories and aspirations. But the politician could not work with serks and forceps, test tubes and mortars, his instruments were written and spoken words, so that politics could never be an exact science. The perils of the platform orator had been pointed out since the days of Cleon. The difference between the Greek sophists and the modern demagogues was said to consist in this: that the former displayed his ingenuity by appearing to prove what his hearers knew to be false, while the other displayed his ingenuity by appearing to prove what his hearers wished to be true. It was the business of the universities to change all this, and they were doing it, they should take their stand on public right and a law of nations with Grotius rather than with Machiavelli. This principle had asserted itself in August, 1914, when it was made plain that ethics was not a branch of politics but the reverse, and it was at the root of their support of the League of Nations.

Mr. Baldwin was entertained at luncheon after the rectorial address by the Edinburgh University Union, and in the course of the afternoon he visited the Edinburgh University Settlement in High School Yards. In the

evening the students held a torchlight procession, at which a collection was taken up on behalf of the Royal Infirmary of Edinburgh.

GLASGOW HOSPITAL FOR WOMEN

In submitting the directors' report to the forty-eighth annual meeting of subscribers to the Glasgow Hospital for Women, on November 3rd, Mr. H. Stuart Curran, honorary secretary, stated that out-patient consultations had numbered 4,482, an increase of 432 over last year. The annual revenue had amounted to £1,978 and the expenditure to £2,487. The directors noted with satisfaction that there had been an increase of subscriptions received from employees of works, while a sum of £1,093 had been contributed by patients. In the medical report it was stated that the work at the hospital was steadily increasing, but that greater in-patient accommodation was required, as cases often had to be treated outside the institution on account of lack of accommodation.

England and Wales.

TREATMENT OF CRIPPLES IN WALES

A CONFERENCE of representatives of health authorities in Wales was held at Wrexham on November 6th to discuss the best means to be adopted for the treatment of crippled children. Dr. D. Llewellyn Williams, the medical member of the Welsh Board of Health, was in the chair, and Sir John Lynn Thomas gave an address, in which he emphasised the necessity for early treatment by persons specially trained in the care of crippled children. He expressed the hope that provision would be made in connexion with the Prince of Wales's Hospital at Cardiff to give surgeons special opportunities of studying orthopaedic treatment. The conference unanimously adopted a resolution in favour of the formation of a Welsh branch of the Council for the Cure of Cripples which has been established in England.

ST. PETER'S HOSPITAL FOR STONE

The story of a small but very well known special hospital was retold at the appeal dinner held at the Hotel Victoria, London, on November 5th, on behalf of St. Peter's, in Covent Garden, which is devoted to the treatment of stone in the bladder and minor diseases generally. The Royal Family, represented by the Marquess of Crisbrooke, who presided, the peerage, by Lord Warrington, the Bar, by Sir Patrick Hastings, the world of business, by Sir Howard Frank, as well as the medical profession, by several distinguished members, bore testimony to the hospital's usefulness. The result of the appeal, announced before the close, was a sum of nearly £4,000, which will go some distance, though by no means all the way, towards providing the modernized operating theatre, the enlarged quarters for nurses, the cost of the recently installed X-ray equipment, and other extensions which are necessary. The Marquess of Crisbrooke said that the hospital was established sixty-five years ago, and for half a century it remained the only hospital of its kind. The urological departments now existing in large general hospitals might be regarded as the children of St. Peter's. He mentioned that over 100 cases were awaiting admission to its thirty-two beds. Sir Patrick Hastings, in a moving speech, said that however different the views which might be entertained even in this gathering concerning the future of voluntary hospitals, they would all agree that in this country there existed the finest hospital system in the world, one which made the highest medical and surgical skill available to the poorest citizen. Sir Thomas Holder, in proposing the health of the surgical staff, pleaded that special hospitals had a function which large general hospitals with special departments could never discharge. When it came to making a thorough study of a special subject recourse must be had to these small special institutions, it was from these rather than from the general hospital that additions to knowledge was the result of research had emanated. They had the advantage of bringing into close daily association men engaged on the same line of work and they were also very convenient

centies for post-graduate instruction. What little he himself knew of thiornts he had learned at Golden Square, what he knew of eyes, at Moorfields, and if his career had been in surgery he would have derived his knowledge of the treatment of urological conditions by surgical procedure at St Peter's. He paid a tribute to those associated with the hospital in the past, especially the late Sir Spencer Wells and the late Sir Peter Freyer, to the present consulting surgeons, Mr Swinford Edwards and Mr Henry Fenwick, and to the present surgical staff, Sir John Thomson Walker, Mr Swift Joly, Mr A. C. Monson, Mr F. J. Barrington, Mr Ogier Ward, and Mr Alban Andrews. In responding, Sir John Thomson-Walker referred to the world-wide reputation of the hospital. He said that if in any clinic in Europe or America a case came forward of the kind with which St Peter's had to deal, the name of St Peter's would almost certainly be mentioned, or the name of some member of its past or present staff, or there would be some indirect allusion. This reputation had been built up by steady and continuous good work. Old methods had been revised and brought up to date, and new methods introduced. The knowledge gained was regarded by the staff as a trust to be imparted as widely as possible. He mentioned that during a tour he undertook not long ago in Canada, from Quebec to Vancouver, 60 per cent of the medical men to whom he spoke had visited St Peter's.

Ireland.

REDUCED DEATH RATE FROM TUBERCULOSIS

At the inaugural annual meeting of the Medical Society of University College, Dublin, the President, Dr W. D. O'Kelly, Professor of Pathology, University College, read a paper on the epidemiology of tuberculosis. The tuberculosis test showed, he said, that by the time they had reached their twelfth year 70 per cent of children had become infected, in the case of children living with tuberculous parents this figure was reached much sooner. The death returns showed that one in every nine or ten deaths in these islands was caused by tuberculosis. Least fatal in the school age, the mortality rose rapidly after the fifteenth year, the female being more liable to die at this period. Before the twenty-fifth year, with the mortality still rising, the death rate in males exceeded that in females, and continued higher throughout the remaining span of life. The maximum mortality in males was reached at about the fiftieth year—twice as high as that occurring in the female. This was specially noticeable in industrial countries like England, but in Ireland the maximum in males and females occurred between the ages of 20 and 35. To some extent the mortality depended upon housing conditions, but the nature of the occupations was all-important. Infection with the bovine type of bacillus was frequent, especially among the young. This could only be attributed to the use of milk from tuberculous cows. Thirty to fifty per cent of cows in Ireland were, some years ago, tuberculous, but only 1 per cent had diseased udders. Yet their milk might be mixed with that of healthy cows, so that something like 8.16 per cent of city milk contained tubercle bacilli. Instancing the infectivity of such milk, he cited an experiment in which one ten-millionth of a cubic centimetre of the milk set up generalized tuberculosis in a guinea pig. This risk could be eliminated by securing a good milk supply. Although common in early life, the human type of tubercle bacillus was much more frequently met with in man after the sixteenth year. It caused bone and joint tuberculosis, meningitis and pulmonary tuberculosis, was almost entirely due to it. Overwork, strain, pregnancy and bad health might light up the disease in adult life. It was often stated that the Irish race was particularly susceptible to tuberculosis, but Professor O'Kelly thought that when corrected death rates were compared the position might not look so bad. He admitted that the death rate from tuberculosis was high. It rose steadily in the years 1865-1900 but the campaign initiated by Lady Aberdeen brought a marked change. Since 1908 the death rate had steadily declined and now was little

more than half of what it was in 1907. There had been a marked falling off in the mortality from tuberculosis in infancy. In 1907 tuberculosis caused 11,679 deaths, but in 1923 about 4,000 only. In 1918 the mortality from influenza was 2,432 per million persons living, but the mortality from tuberculosis had never reached so low a figure during the thirty years 1879-1909. The end of tuberculosis was, the lecturer suggested, in sight. Osler had foretold a 50 per cent reduction in the mortality of the disease in Ireland within a generation, and he had nearly lived to see his prophecy fulfilled. The lecture was illustrated with lantern slides, which showed wonderful results achieved in the treatment of tuberculosis by sun light and ultra-violet rays. Sir William Thompson, in proposing a vote of thanks, spoke of the treatment of tuberculosis in the Franco State. He considered that the result of sanatorium treatment would be much better if something was done for advanced sufferers, for the convalescents, and for the sanatorium patients during the period from discharge to resumption of work. But if the disease was to be completely eradicated preventive measures must be taken. The question, What is meant by prevention? arose. For prevention the standard of living must be raised, housing conditions, wages, and the home life improved.

Correspondence.

RAW PANCREAS BY MOUTH COMPARED WITH INSULIN

SIR,—I feel that I cannot let Dr Bernstein's note of November 7th (p. 844) pass without a protest that he has given in his tables none of the essential facts necessary to prove the efficacy of raw pancreas by mouth in the treatment of diabetes. He makes no mention of the diet of his patients, whether it was weighed and closely supervised, or even whether it remained constant from month to month. Nor does he state whether the time of the blood sugar tests in relation to meals was always the same—a point of great importance. Only when these data are available can his tables be considered as serious evidence that raw pancreas has any effect in diabetes.

In the recent discussion in your columns, all investigators who have carefully controlled all the factors have found raw pancreas quite useless—I am, etc.,

London, W 1, Nov. 7th.

R. D. LAWRENCE

PLANT POISONING

SIR,—In the report of the Section of Comparative Medicine of the Royal Society of Medicine in the *BRITISH MEDICAL JOURNAL* (November 7th, p. 847) Dr W. H. Andrews, in his interesting paper on plant poisoning, expresses the opinion that further investigations should be conducted by biologists, chemists, and pharmacologists. The role he would assign to the first of these is to determine whether any specific plant is or is not poisonous to any specific species of animal, and, if so, in what circumstances and to what animals. May I suggest that to this should be added an experimental inquiry as to what extent, if any, the young and inexperienced of animals—the herbivora, for example—when freshly weaned from their mothers, consume plants possessing toxicity to themselves. It is of interest to record the fact that some 2,000 years ago the great evolutionary poet Lucretius, in his *De Rerum Natura*, called attention to some of the very points discussed at the Royal Society of Medicine on October 28th, 1925.

Leaves of wild olives yield a sweet repast
To Goats to Man a rough and bitter taste
Thus pigs fly sweetest odours those that please
And tickle Man offend and poison these
Yet they will roll in dung in filth delight
Though squeamish Man can scarce endure the sight.

And again

'Strong poison unto me another loves,
And eats and lives. Thus Hemlock juice prevails
And kills a Man but fattens Goats and Quails.'

—I am, etc.,

Chatham Nov. 7th

C. MARSH BROADLEY,
Surgeon Rear Admiral R.N.

PROPHYLAXIS OF TUBERCULOSIS IN INFANCY AND CHILDHOOD

The Grancher System

Sir,—The Grancher system is acknowledged to be scientifically sound, but, apart from the financial difficulty, there is one great obstacle which prevents it being carried out on a large scale—namely, the objection of parents to allow their children to be sent away. To the parent stricken with tuberculosis, the suggestion of such a separation often brings overwhelming distress, and consent is refused, however desirable this step may be in the interests of the children in the long run. It appears from Dr Bolton Tomson's letter (November 7th, p 866) that at Hastings the children are only boarded out in the "spring, summer, and early autumn months," that the average stay is from four to five months, and that only children in failing health and those in an early stage of tuberculosis are sent to allow children who are in poor health to go to the country for a few months in the summer, but that is not the Grancher system as I understand it. Dr Armand Dehille in his paper read at the Tuberculosis Conference in London in 1921 said that the children boarded out under the Grancher system in France are taken away while still perfectly healthy, as long as it is necessary for the disappearance of contagion in their own family. This disappearance becomes sometimes happily a cure, but more often the death of the tuberculous parent. This demands in average of three years.

It appears to me that although the number of cases where it is practicable to carry out the system will be limited, it is on lines such as described by Dr Armand Dehille that we must work if it is to be a real protection of these children against tuberculosis.—I am, etc,

ARTHUR C. WATKIN,
Tuberculosis Officer, Shropshire

November 9th

Sir,—Dr W Bolton Tomson (November 7th, p 866) and your readers may be interested to know that there is a Plymouth and District Hostel for the children of tuberculous parents established and at work. The London County Council is also doing similar prophylactic work. The Plymouth system accommodates the children in a pleasantly situated obsolete bungalow, rented from the War Office, and has resident foster-parents there. A boarding-out system will be added when possible. Our system is based on Leon Bernard's principles combined with those of Grancher, but we are not yet taking "contact" children under 3 years of age. We contemplate, however, linking up infantile prophylaxis with creche and accouchement centres (Leon Bernard's system at the Hotel Lemoine), and finally with the Grancher system for children of school age.

I have all the literature of Dehille and Bernard available on the subject, and shall be pleased to afford any information at my disposal to anyone interested. Our results generally have been excellent and encouraging, and confirm the opinion I formed from visits to "preventoria" in France, and what I heard first hand in Paris, Brussels, Bordeaux and London. The medical officer of health for Plymouth, Dr A T Nankivell, is interested in the hostel.—I am, etc,

November 7th

F G BUSHNELL,
Chairman and Medical Officer, Plymouth and District Hostel for the Children of Tuberculous Parents, etc

OSTEOPATHY AND CHIROPRACTIC

Sir,—In your issue of November 7th (p 868) Dr J S Manson, in dealing with the proposed registration of osteopaths, publicly decries of the commonwealth, not without a fairly plain hint of the culprits responsible for his sackcloth and ashes. There weighs upon him the conclusion that neither individually nor collectively is the medical profession likely to express or to organize opposition to a scheme which would imply State recognition of persons who have not been trained or examined as the law at present

directs. And the ground for this conclusion seems to be the non acceptance by the Representative Meeting at Bath of a motion that the medical profession should endeavour through legislative action to ensure "that no unqualified person be allowed to practise medicine or surgery."

Dr Manson is, of course, perfectly free to deplore the decision of the Representative Meeting, but by what process of reasoning he interprets this decision to mean an acquiescence in the construction of a State register of osteopaths I am unable to imagine. Surely it is possible to decline to embark upon a crusade to "put down" unqualified practice by force of law, and yet to object to an official registration of unqualified practitioners. Because some of us felt ourselves unable to follow Dr Manson's "lead" towards a campaign of prosecutions and penalties we must not be reproved as "sympathetic" towards an entirely different proposition.

Had Dr Manson asked the Representative Meeting to express an opinion on an official recognition of any group of groups of unqualified practitioners he would probably have received an answer very different from the one which to judge from his letter, appears to have plunged his mind in an atmosphere of unrelieved gloom. His proposal is not of this order, and it was declined. Hence these tears.—I am, etc,

London W 1, Nov 9th

C O HAWTHORNE

Sir,—As the years pass many medical practitioners realize that the average medical education tends to create a physician or surgeon who is admirably fitted to deal with the emergencies of sudden illness and accident which demand prompt decision and urgent treatment. Many of the chronic ailments, in which body and mind are so inextricably and inextricably mingled do not respond so readily to the methods of treatment by diet and drugs which are taught in the scientific curriculum. For dealing with those obscure cases other qualities are required—common sense and a special "flair" for adapting the best of several available methods to the special psychology of the individual. Therefore those whose work lies chiefly with the innumerable forms of chronic minor diseases find that in order to obtain successful results they have to concentrate on definite lines of treatment in the administration of which they gradually become expert. Thus there are spheres of usefulness for the vaccine therapist, the psychotherapist, the electrotherapist, the specialist in the treatment of various organs, in massage, in orthopedics, in x-ray and radiotherapy. Of recent years the need as well as the demand for these methods of treatment has led to the formation of special post-graduate courses of instruction. Already a diploma (D M R E) has been arranged by those whom experience had convinced of the great therapeutic value of electricity when employed by experts who know exactly how to use it.

It is certain that there is much value in treating the reflex centres along the spine, and much scientific study on this subject remains to be done. Those who work with electricity have recognized for a generation the tonic effect (surpassing that of drugs) which is obtained by treatment directed to the lower cervical and upper dorsal the lower dorsal and lumbar regions of the spine. How and why these results are obtained is still a matter of controversy. There are already many qualified medical practitioners who use manipulative methods upon the spinal centres. The work of Cyriax and others who have specialized in manipulative massage and many cases of chronic spinal pain and circulatory engorgement of the head and neck. It is impossible for every qualified practitioner to learn every branch of treatment. Even if a seven or eight years study enabled him to have some knowledge of every branch of treatment no matter how well trained and instructed a man may be his personality, experience and judgement play a large part in the cure of the patient who suffers from chronic ailments. We hear so little of the successes of the osteopaths and numerous other cults of mental and physical healers? Every medical practitioner comes

across many of these failures and cures them. But how can this be explained to the layman?—I am, etc.,

London, W 1 Nov 4th

AGNES SAVILL

SIR,—Although I am opposed to any State recognition of semi-qualified persons, there can be little doubt that many of the medical profession are too apt to brush aside anything coming from outside its folds. Pasteur's fight with the French Academy is a case in point, and Gentry's masterpiece emphasizes the absurdity of imagining that nothing of value can come except from within the fold. From time to time men appear who, holding no academic degrees, yet give to the world something of great value. After all, we as medical men or women should inquire into anything and everything that may be beneficial to mankind. Much may be rubbish, but now and then a diamond may be found. Any water-tight compartment policy lays us open to deserved public censure.

Incidentally, during the war, I offered the run of the hospitals, over which I had the honour of being in charge, to a well known osteopath, my object being to give the unfortunates under my care the benefit of this gentleman's supposed special knowledge. I offered to undergo a course of instruction, pay for it, attend anywhere and any time. No one man can possibly see every case, but he can instruct others and so broadcast his skill. My offer was not accepted, and I am still waiting a reply to my second letter in which I asked to be allowed to attend his clinics or anything else.

This year I received a letter from the secretary of an osteopathic clinic, pointing out the value of the work done. It once more asked to be allowed to attend for instruction and observation. I had conversations with one of the osteopathic doctors, read some of the medical books he kindly sent me, but my suggestion of my attending the clinic met with a negative response.

An osteopath is usually definite in what he can do. This gains the patients' confidence. The results may or may not be successful, we hear of the successful ones only, the man who says that he has never had a failure has either no practice or is the other thing.

Because one great man appears outside an academic profession all who follow in his footsteps are not necessarily great, therefore the cry that all should be admitted to State recognition is fallacious. We know of a certain man, still alive but for the moment removed, whose logical knowledge is said to equal that of any State recognized lawyer. Will any of the courts admit him on this plea into their very seclusion bodies?—I am, etc.,

London SW 7 Nov 7th

A MACBETH ELLIOT, M D

A LETTER OF THANKS

SIR,—I am returning to Moscow after a visit of three weeks to England as the representative of the Russian Endocrinological Association. Mrs I, through the columns of your esteemed JOURNAL, express my thanks for the courtesy with which I was so readily afforded opportunities for visiting your leading hospitals and medical institutions, and for the great kindness extended to me by the many professors and medical men whom I had the pleasure of meeting there?

I was fortunate in being granted introductions, and at all hospitals and institutions unfailing courtesy was shown to me and services were willingly placed at my disposal. My visit to London was made most interesting, and it has been most gratifying to learn of the enormous progress made in your country, in regard to questions concerning infant mortality and scientific research work, since my last visit to England eleven years ago.

It has given me great pleasure to realize, from the attitude shown to me at the hospitals and institutions I visited, and from the very interesting talks I had with many of your leading professors and medical men, that scientific relations between England and my country are becoming firmer, and, through your medium, I again desire to express my deep appreciation of the co-operative spirit shown to me by all those members of the English medical profession I had the honour of meeting during my visit.—I am, etc.,

Paris Oct 25th.

EUGENE WILKIN, M D

RHEUMATOID ARTHRITIS

SIR,—As a general practitioner, might I crave your indulgence for a few remarks in regard to the recent discussion in the JOURNAL on the treatment of chronic arthritis? In the first place, is rheumatoid arthritis to be considered a distinct entity, or simply the end result of a number of various and dissimilar factors? Briefly, is there such a disease as rheumatoid arthritis *per se*? From the opinions expressed by our teachers and those of our profession best qualified to pronounce judgement I must confess that I am at a loss to draw any clear conclusion.

Unfortunately, I am a victim of osteo-arthritis, and also subject to acute and chronic attacks of fibrositis with the formation of nodules, particularly in the lumbar fasciae, and am therefore of the opinion that the *fons et origo mali* is the same in both complaints.

Professor Wild's exacerbations with a falling barometer and humid atmosphere are exactly my own. The various forms of arthritis, fibrositis, etc., designated as rheumatoid seem to point to some error or defect of metabolism. The tissues which bear the brunt of the disease are the same as those we find affected in gout. In fact, they may be looked upon as kindred complaints, but while gout can be cured by dietetic and therapeutic measures, and probably in another generation will be extinct, there is no such optimistic outlook for the unfortunate victim of rheumatoid arthritis. Perhaps the solution may be in the hands of the chemist or biochemist. Osteo-arthritis is a universal concomitant of old age in man and all mammals, and the oldest known disease. Even the Pharaohs were not immune, and the fossilized bones of the extinct Irish elk show that before the dawn of history the animal was a sufferer.

Any effective remedy would be one of the greatest therapeutic blessings conferred on suffering mankind in this or in any other age.—I am, etc.,

October 12th

A VICTIM

Universities and Colleges.

UNIVERSITY OF OXFORD

THE degree days in the present academic year are as follows: Saturday, November 14th; Thursday, December 17th; Thursday, January 21st, 1926; Saturday, February 13th; Saturday, March 27th; Thursday, April 29th; Saturday, May 22nd; Thursday, June 24th; Saturday, July 3rd.

Entrance scholarships and exhibitions have recently been awarded to the undermentioned members of the Oxford Medical School at the hospitals named—Guy's Hospital O A Beadle (New Coll), L T Ride (New Coll), King's College Hospital C F J Cropper (University), A W Cabbitt (Wadham), W G Rees (Jesus), St George's Hospital H E Mansell (Pembroke), St Mary's Hospital D H Brinton (New Coll), W Hurst Brown (Queen's), Westminster Hospital W R Greco (Pembroke), A T Leslie Spinks (Oriel), M G Pearson (Keble), H G Wells (Magdalen).

A decree was passed in Convocation on November 10th accepting the sum of £2,200, a bequest by Mrs Constance Jenkinson, for the endowment of a lectureship in comparative and experimental embryology, in memory of her husband, John Wilfred Jenkinson (Queen's). Westminster Hospital W R Greco (Pembroke), A T Leslie Spinks (Oriel), M G Pearson (Keble), H G Wells (Magdalen).

UNIVERSITY OF CAMBRIDGE

Pinset Darwin Studentship in Mental Pathology

THIS studentship was founded in 1924 by the bequest of Mrs Pinset and Sir Horace and Lady Darwin for the purpose of promoting research into any problem which may have a bearing on mental defects, diseases, or disorders. The studentship is of the annual value of about £200 and is tenable for three years in the first instance. The student (who may be of either sex and need not be a member of the University of Cambridge) must engage in original research in Cambridge or elsewhere, but may, subject to the consent of the managers, carry on educational or other work concurrently. Further particulars of the studentship may be obtained from the Registrar of the University of Cambridge and applications for appointment to the studentship should be sent before December 1st, 1925 to the Secretary of the Studentship, Psychological Laboratory, should state their age and qualifications, the problems in which they are interested and should give the date at which they would be prepared to begin work if appointed. No testimonials are required but applicants should give the names of not more than three referees.

UNIVERSITY OF LONDON

A MEETING of the Senate was held on October 21st. The following were recognized as teachers of the University in the subjects and at the institutions indicated:

St Bartholomew's Hospital Medical School—Mr Hugh E Griffiths (anatomy), Dr James W D Scott (physiology), Mr Arthur Edmond (anatomy), Mr Noel St J Dudley Burton (anatomy), Mr Cecil G Valerius (surgery), *London School of Hygiene and Tropical Medicine*—Mr Andrew Robertson (protozoology).

The resignation by Professor A V Hill, Sc D, of the Todrell Chair of Physiology tenable at University College was accepted, with effect from December 31st, 1925. We believe, however, that this will not terminate Professor Hill's connexion with University College.

A bequest from the late Sir Rickman Godlee, Bt, by which, after the death of his wife one moiety of his residuary estate is given to University College and the other moiety to University College Hospital, was accepted.

The Senate accorded its thanks to Dr O. Inghley for his offer to contribute £10 a year for ten years towards the cost of a prize in pharmacology at King's College.

The regulations for the Dunn Exhibitions in Anatomy and Physiology (Red Book 1925-26 p 265, and Blue Book September, 1925, p 232) were amended by the insertion in the fifth line of the words "at the March examination" after the words "shall be awarded."

The following appointments of examiners were announced: Mr C H S Frankau to succeed Mr G Gordon Layton (resigned) as staff examiner in surgery at the M B B S examination, Mr B R Carling to be associate examiner in surgery at the M B B S examination, vice Mr Frankau, Mr A G Boulerton to succeed Sir F M Legge (resigned) as staff examiner in State Medicine at the M D examination.

The External Council reported that Dr R T Williamson one of the staff examiners in medicine, was unable to act at the forthcoming M B B S examination on account of ill health, and that the Vice-Chancellor had appointed Dr Gordon Holmes, an associate examiner to act in his place and had also appointed Dr E P Poulton to act as associate examiner in the place of Dr Holmes.

Essays or dissertations for the Rogers Prize on the value of the methods of investigating diseases of the pancreas should reach the Vice-Chancellor at the University on or before April 1st 1926. Further information regarding the prize (value £100), which is open to all persons whose names appear on the *Medical Register* of the United Kingdom, may be obtained on application to the Academic Registrar.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

The following officers have been elected for 1925-26: President, Mr R M Buchanan, Visitor, Dr G H Lindington, Treasurer, Mr J H MacDonald, Honorary Librarian, Dr L H L Oliphant.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the President and Fellows held on Friday November 6th, Sir James Ram Males, L R C P Lond, M R C S Eng, and M R C P Edin, having passed the necessary examination, of the College.

Dr Bethel Solomonson was appointed an associate examiner in practice midwifery, and Dr Robert A MacLavery was appointed an examiner in gynaecology and obstetrics for the membership.

The Services

The sixth annual dinner of the medical officers of No. 14 Stationary Hospital will be held on Friday December 4th at the Trocadero Restaurant Piccadilly at 7.45 p.m. Lieut Colonel J R Harper, CBE will be in the chair. The price of the dinner will be 15s (exclusive of wine). Evening dress or dinner jacket, miniature medals optional. The honorary secretaries are Major H M Perry and Dr H L Tidy, 39 Devonshire Place W1.

DEATHS IN THE SERVICES

Lieut Colonel Peter Thomas Frazer R A M C (ret.) died at Bournemouth on October 24th, aged 80. He was educated in Dublin at the Medical School of the Royal College of Surgeons in Ireland and took the L R C S I and L R C P in 1867. He entered the army as assistant surgeon in 1868, became surgeon major after twelve years' service and retired in April 1888. As a regimental officer he served in the 16th Lancers. He took part in the Afghan war in 1879, was present at the forcing of the Khyber Pass and received the medal.

Major George King Indian Medical Service (ret.) died at Corstorphine Middlethian on September 23rd, aged 54. He was educated at Edinburgh where he graduated M B and Ch M in 1896. After acting as demonstrator of anatomy in the Royal College of Surgeons School as clinical assistant in the Royal Hospital for Sick Children and as resident surgeon to the Royal Maternity Hospital Edinburgh he entered the Indian Medical Service in January 1899, became major in 1910, and retired in February 1917. Most of his service was spent in civil employ in the province of Bengal.

Obituary

J N LANGLEY, Sc D, Hon M D, LL D, F R S,

Professor of Physiology in the University of Cambridge

We regret to record the death, on November 5th, of Professor J N Langley, who had held the chair of physiology at Cambridge for the past twenty-two years. An estimate of his pioneer work in experimental physiology, and of the great place he held in the realm of biological science, will be found in the tributes from colleagues, which we have the privilege of printing below.

John Newport Langley was born in 1852, and entered St John's College, Cambridge, from Exeter Grammar School with a scholarship in 1871. He soon came under the influence of Michael Foster (who had just been appointed to the new post of Praelector in Physiology at Trinity College), and obtained a first-class in the Natural Sciences Tripos of 1874. Then began the long series of brilliant investigations into the physiology of the visceral nervous system, which made the name of Langley famous throughout the scientific world. In 1877 he was elected to a Fellowship at Trinity, and after acting for some time as one of Foster's demonstrators was appointed university lecturer in physiology in 1884. In 1900 he undertook the duties of deputy professor, and in 1903, on Sir Michael Foster's retirement, was appointed to succeed him as professor. In 1883 he was elected F R S, in 1892 he received a Royal Medal, and in 1904-05 served as vice-president of the Royal Society. He was president of the Neurological Society of Great Britain in 1893 and of the Physiological Section of the British Association in 1899, and Baly medallist of the Royal College of Physicians of London in 1903. For more than thirty years he edited the *Journal of Physiology*, at first in association with Michael Foster. His many academic distinctions included the honorary degrees of LL D St Andrews, Sc D Dublin, and M D of Groningen and Strasbourg. He was a corresponding member of the Société de Biologie, Paris, and the Imperial Academy of Medicine, Petrograd, honorary member of the Swedish Society of Physicians, the Belgian Royal Academy of Medicine, and of many European physiological and biological societies.

When the British Medical Association held its first Annual Meeting after the war at Cambridge, in 1920, Professor Langley took a warm interest in the arrangements made by the University for this visit, and, as vice-president of the Section of Physiology and Pharmacology, opened a discussion on the treatment of denervated muscle and on the "disuse" theory. The object of his paper was to put before a medical audience some results of the laboratory investigations he had carried out during the war into the degeneration of muscle and regeneration of nerve with a special eye to recovery after suture. His conclusion—not too cheering perhaps, to the electrotherapist and the physiotherapist—was that the treatment of denervated muscle must be regarded as still in the experimental stage.

Cambridge

Sir Humphry Rolleston, Bart, F R C P, Regius Professor of Physics at Cambridge, writes:

The death of Professor J N Langley, the leader of the Physiological School, following on the loss of Sir Clifford Allbutt, the doyen of British medicine, has been an irreparable blow to Cambridge. He lectured as recently as October 31st, and was busily engaged in experimental work up to the onset of the pneumonia which carried him beyond the veil on November 5th. Educated at St John's College and taking a first class in the Natural Sciences Tripos he was, after a close contest with A Sheridan Leys, elected a Fellow of Trinity, thus following the example of Richard Bentley, the great Master of Trinity (1700-1742), who is supposed to have remarked "With the help of God I got over the wall." Sir Michael Foster organized the Physiological School, and inspired Gascoigne, Langley, Sheridan Leys, and other pupils with the ideals of research which raised British physiology to its pre-eminent position.

Langley, who succeeded him as professor in 1903 and is editor of the *Journal of Physiology* (really from 1894), was for years a lecturer on advanced physiology, and in the middle eighties I had the great advantage of coming under the kindly and stimulating influence. His early work on the zymogen granules in the cells of secreting glands, though not undertaken with any idea of application to the practice of our profession, has, like his subsequent investigations on the autonomic system extending over some thirty-five years, been of the greatest importance in connexion with the problem of present-day medicine. Gaskell's genius first established the broad lines of the general arrangement of the nervous system, and Langley carried on this task and added much, both in principles and in details, to our knowledge, for example, in connexion with pharmacology and the endocrine system. In contrast to Foster, he was essentially an experimenter and communicated his enthusiasm to many pupils, such as Sir Charles Sherrington, the late A. S. Granbaum, the late Ice Dickinson, whom he associated with himself in the brilliant discovery of the paralyzing effect of nicotine on the sympathetic at the junction of the white ramus with the ganglion cells, and Sir Hugh K. Anderson, now Master of Corpus College, who collaborated with him in further experiments on the autonomic system. His papers in the *Journal of Physiology* numbered about a hundred, and our knowledge of the subject which he had more specially made his own is summarized in his work *The Autonomic Nervous System*, the first part of which appeared in 1921, and was reviewed in this JOURNAL (1922, 1, 230). As an editor he was extraordinarily conscientious, wisely critical, and set up both for himself and for others a very high standard of accuracy and argument. As an organizer and administrator it was obvious that the mantle of his predecessor had fallen on most competent shoulders, and thus, if proof were needed, is shown by the results of his supervision of the construction of the new physiological laboratory opened in 1914. It is a pathetic coincidence that the current number of the Rockefeller Foundation's *Methods and Problems of Medical Education* (third series), which came to hand on November 5th, should contain a full account of his departure from his own land. As a patient and pioneer research worker he was indeed an outstanding example of the importance of relying on solid observation and of resisting the attractions and attendant fallacies of hypotheses. Essentially a shy soul, he had an air of reticence which some could neither understand nor penetrate. It is as a willing guide and charming friend that I mainly think of him, some forty years ago, making an occasional companion of one of his junior pupils in games and walking tours at home and abroad. Generous in all things, and with many outside interests—literature, travelling, skating, and gardening—he was much younger, both in mind and appearance, than his years suggested, and his death in the full tide of his activities is sadly premature.

We are indebted to Sir W. B. HARDY, F.R.S., University Lecturer in Physiology, Cambridge, for the following appreciation.

Langley was one of the small band of workers gathered together in the early seventies by Michael Foster. The physiological department at Cambridge then consisted of a single room—the one now occupied by the philosophical library. All the members of the school were young, including Foster himself—for to the end he never lost his boyish capacity for fun—and stories, his fast fading into oblivion, tell of their enthusiasm for play as well as for work. Francis Mott and Balfour, Dew Smith (who founded the Cambridge Scientific Instrument Company), Newall Martin (who did so much for American physiology), Vines, Bridges, Gaskell, and Langley—they were a notable band. Their early papers were issued as *Studies from the Physiological Laboratory, Cambridge*, to which the *Journal of Physiology* established in 1878, was the successor. As might be expected under Foster the interests of the infant school were wide. They included embryology, comparative anatomy as well as the physiology of animals and plants, for nothing was beyond Foster's sympathy. Langley was almost the last survivor of the band, and when death closed

his career last week he had entered upon his fiftieth year of active research. He was at work until the last, and to the last he taxed his powers to the utmost. A week before his death he was in the laboratory experimenting, without food or rest, for eight hours, and there were then no signs that age had impaired the steadiness of his hand or the sureness of his touch.

The first fifteen years of his active scientific life were devoted almost wholly to the mechanism of glandular secretion, to the relation of the cell granules to the formation of mucus and pepsin, and to the action of the cerebral and sympathetic nerve fibres upon the secretion of saliva. From this last he passed by easy transition to his life work—the study of the sympathetic nervous system. To Gaskell and Langley—the two names cannot be separated—belongs the credit of having built up the major part of our present knowledge. Langley was helped by his discovery that nicotine, applied locally to a ganglion, paralysed the sympathetic nerve fibre at its junction with a nerve cell. This enabled him to map out the path of the fibres to various organs and fix the position of the relay cells upon their course. He also, at a later period, investigated the mechanism through which the nervous impulse starts the contraction of the muscle fibre.

The quantity of his published work must be extraordinary, and the quality was always high. So far as the writer knows, Langley never made a mistake. All that he has written will stand as testimony to his most unusual skill as an experimenter and his capacity for accurate observation and self-criticism. Valuable as were Langley's direct services to science, he rendered mother almost equally valuable as editor of the *Journal of Physiology*, a responsibility which he shouldered in 1894. The titillation of the physiological paper had been that of the "descriptive" sciences. Langley changed it to that of the "exact" sciences, with resulting gain both to readers and authors. He was a great editor as well as a great physiologist.

A man of great natural dignity, knowing his own mind and impatient of delay, he was apt to give an impression of hardness and want of sympathy to those who knew him only superficially. The impression was largely false. Langley did not spend his capacity for friendship recklessly, but when it was called upon he could, and did, give freely. On two occasions known by chance to the author, and there certainly were many others, he rendered services which few would have done.

Sir D. Sharpey Schaffer

Sir EDWARD SHARPEY-SCHAFER, F.R.S., Professor of Physiology, Edinburgh, has, in response to our request, sent the following tribute to his friend's memory.

The death of Professor Langley is a severe blow to physiology, in which, as an investigator of certain subjects, he was *facile princeps*. His loss will be felt not only in this country but throughout the world. At the triennial Congresses of Physiology no one will be more missed, for he was always present, and took an influential part in the proceedings.

The outstanding feature of Langley's work is the accuracy of observation which throughout characterizes it. So far as I am aware no statement of fact that he has made, although frequently based only on unaided ocular observations, has ever been seriously questioned. And most of the generalizations which we owe to him—such as the law of distribution of the autonomic nerves, and that concerning the "receptive substance" of the cell—have been so universally accepted that they have come to be regarded as axiomatic. It may be said without fear of contradiction that no more solid contributions to physiology than those of Langley have issued from any physiological centre. It has, indeed, been a surprise to his friends that his work has never found the recognition by the Nobel Committee it has seemed to deserve. For whatever its nature—whether secretion, or nervous functions, or the action of drugs, or degeneration processes in nerve and muscle—there was no subject of which he undertook the investigation without illuminating it. Moreover, his work furnishes a striking example of the importance of keeping microscopic observation in close touch with physiology.

I have known Langley intimately for more than

fifty years. The last occasion we met was at the International Physiological Congress which was held in Edinburgh in 1923. He then appeared as vigorous, not to say as youthful, as ever, and looked as if he might easily enjoy at least another decade of active scientific life. But the fates have willed it otherwise, and we, his old colleagues and friends, can, alas! do no more than express our regret for the loss we have sustained by his untimely death.

Sir Charles Sherrington

SIR CHARLES SHERRINGTON, F.R.S., Professor of Physiology, Oxford, has sent us the following:

The invitation to submit some words of tribute to the memory of Professor Langley is a privilege valued by me, not only as one who, in common with all those who pursue physiology, admires his work and deeply regrets his loss, but also as one who was his pupil and owes him that kind of personal debt which lifelong gratitude alone can attempt to repay. To work under him or with him was to see exemplified a fidelity of observation, a detachment from preconception, and an untiring search for new facts which formed at once a lesson in character and an inspiration for method. It is unnecessary here to bear witness to the importance of his achievements, his discoveries speak for themselves. He was in many respects a pioneer, not least so in that, without having received formal training in medicine, he yet chose to devote his life to physiology. His gift of minute observation was such that in his hands simple inspection was often as reliable as graphic registration by recording instruments. He was always on his guard against deception by technique. This was early and typically shown in his studies on secretion, there, though an expert histologist, he was not content to pin his faith to the appearances of his fixed and stained preparations, decisive though these seemed, but he systematically controlled them by observations taken from the living, though perishable, tissue itself. He will be remembered as one of the makers of that renaissance of British physiology which was one of the features of the scientific progress of his time.

E. J. DOMVILLE, OBE, LRCP, MRCS,

Consulting Surgeon to the Royal Devon and Exeter Hospital.

Very many members of the British Medical Association who knew of the excellence of the work he unassumingly did for it will learn with great regret of the death of Mr. Domville of Exeter. The announcement came as a surprise to many of his friends in Exeter, for though he had retired from practice some years ago and was living at Symondsburry, Dorsetshire, he was until recently quite often seen in Exeter, apparently in good health.

Edward James Domville was the son of a naval chaplain, and was born at St. Ives, in Cornwall, seventy-six years ago. He studied medicine at Guy's Hospital and obtained the diplomas of MRCS Eng. in 1871 and LRCP F Lond. in 1872. After serving a term as house-surgeon to the Royal Devon and Exeter Hospital he later on started in private practice in Exeter, in 1885 he was appointed to the honorary staff of the hospital as surgeon, and continued diligently to discharge the duties of that office until shortly before he left Exeter to live in the country.

Mr. Domville's association with the hospital was in some respects unique in character. He twice filled the appointment of senior house surgeon. At his first appointment he was the youngest house-surgeon the hospital had ever had. His second appointment came soon after the outbreak of the late war, when he emerged from his then recent retirement from Exeter and practice to take up the post as the best form of practical war service he could devise for himself, perhaps during no period of his professional life more than in those war years were his dominating characteristics of superabundant energy and forcefulness combined with kindness more manifest. On the conclusion of the war, therefore, he retired with the thanks of the governors of the hospital, who further expressed their appreciation in tangible form by the gift of a grandfather clock. He was also made an officer of the Order of the British Empire. At this latter period, also, the formation of a venereal centre in Exeter was due to his initiative and he acted as its first

medical officer. Since the war his energy and influence were used to the full in bringing about, despite strong opposition, the erection of the costly new block of buildings known as the Victory Wing of the Royal Devon and Exeter Hospital.

Mr. Domville joined the British Medical Association in 1884, and eventually came to take a great interest in its affairs, both local and central. He had been for many years vice-president of the South-Western Branch, when in 1907 he was elected its president. In that year the Association held its Annual Meeting in Exeter, and Domville was vice-president of the Section of Surgery. He was Chairman of the Exeter Division, 1911-12. Centrally he served on the Public Health, Hospitals, and Ministry of Health Committees, and on various subcommittees, and from 1907 to 1913 was a member of the Central Council. His services in these various capacities were very greatly valued by his fellow members, who appreciated his wide knowledge of affairs and his unflinching courtesy.

In 1920 Mr. Domville took the lead in appealing to medical men to subscribe to a fund to establish a memorial to Sir Victor Horsley. A general committee was formed and received subscriptions from all parts of the world. The committee, over which Sir Charles Ballance presided, and of which Sir Frederick Mott was treasurer, Sir William Albuthnot Lane and Mr. Domville being honorary secretaries, decided that the sum collected, which amounted to over £1,000, should be invested in the name of trustees, who should triennially appoint a person to deliver a lecture in London under the title of the "Victor Horsley Memorial Lecture." Sir Edward Sharpey-Schafer accepted the invitation to give the first lecture, it was delivered in October, 1923, and was on the relations of surgery and physiology. It was printed in our columns at the time (1923, vol. 11, p. 739).

A man of wide interests outside his profession, he took for many years an active interest in municipal affairs, and was a fluent speaker who spoke his mind fearlessly. Becoming an alderman, he was for a time the leader of the Conservative party on the Exeter City Council at a time when party feeling ran very high in that body, and became mayor in 1895, in which year the Church Congress was held in Exeter.

To many of the present generation he was chiefly known for his connexion with the stage. When the old Exeter theatre was destroyed by fire in the early eighties, largely through his efforts another theatre was built on a new site in Longbrook Street, but unhappily that house, too, was destroyed by fire, this time, unfortunately, with terrible loss of life. Mr. Domville thereupon worked again unflinchingly to overcome the sentimental objections to the erection of another theatre on this same site, and finally succeeded. For a long number of years, therefore, he had been the chairman of directors, and formerly also for many years he was the mainspring of the old Exeter Amateur Dramatic Society. Among his other activities he took a keen interest in the university extension movement locally, and was one of those who laid the foundation of the movement which has resulted in the present University College of the South-West. It was also chiefly due to his agency that the Linsborough House Refuge for aged and infirm gentlemen was opened. He was a keen Churchman, and very active in connexion with the Church Defence movement.

In short, though naturally less personally known of recent years to the inhabitants of Exeter, his name will remain, as it has done since his retirement from Exeter, as that of one who led a strenuous, full, and useful life in the service of the community. The large number of people present at the funeral service at St. David's Church, Exeter, to which his cremated remains had been brought overnight, was a striking testimony of the regard in which he was held by all classes. Representatives of many of the organizations with which Mr. Domville had been associated were present, and also the Mayor of Exeter, Sir Robert Newman, M.P., and the Bishop of Crediton, as well as many members of the medical profession.

Mr. Domville married Miss Druce of Exeter, and had a son and a daughter. His son, David, died several years ago. He is survived by Mrs. and Miss Domville.

Dr WILLIAM EDWARD NICHOLAS DUNN, who died on October 19th, at Mentone, was born in 1871, and went from Monmouth Grammar School to St Bartholomew's Hospital. In 1895 he obtained the diplomas M.R.C.S., L.R.C.P., and in 1897 graduated M.B. Lond. He held the appointments of house surgeon to the Metropolitan Hospital, house-physician and resident anaesthetist to St Bartholomew's Hospital, and senior resident medical officer to Queen Charlotte's Maternity Hospital. During the South African war he served as civil surgeon in the hospital ship *Auba*. At the end of the war, owing to impaired health, he began to winter in Egypt, where he became well known, first as medical officer of Messrs Cook's Nile Service, and later in Luxor. During his residence in that town he practised among the visitors there, and devoted much time to the Luxor Hospital for Natives. He was the author of a book entitled *Tunisi as a Health Resort*. During the recent war Mr Dunn served in the R.A.M.C. from 1915 to 1919 at Netley Hospital and the Horton Hospital at Epsom, attaining the rank of major. In consequence of the strain of this work the pulmonary trouble which had threatened for nearly thirty years returned, and he again spent the winters in Egypt from 1920 to 1922. His condition grew steadily worse, and after living for some time in Assoum and Cairo he entered a nursing home at Mentone where he died. A colleague, G. V. W., writes "Bill" Dunn was always a favourite with his fellow students and resident officers, but it was in Luxor that I was closely associated with him and learned to know him well. He was a first-rate practitioner and good anaesthetist. He had his idiosyncrasies, was a staunch, and a very faithful colleague. He was very jealous of the good name of the profession and very plain spoken about anything he considered unworthy or not altogether straight and upright. In spite of the ill health which dogged his footsteps while practising in Luxor, he made a great name amongst very many of his old patients, both British and American, who much appreciated his excellent qualities. With the natives of Egypt he was a great favourite, and in fact with all who came into contact with him. In whatever sphere he worked he would have made his mark. His very numerous friends will much regret his loss.

A veteran West Country practitioner, Dr SYMUR CRADDOCK, died at Bath on November 4th, at the age of 91. He was born at Shepton Mallet, received his medical education at King's College, London, and took the diplomas of M.R.C.S. in 1856 and L.S.A. in 1857. On the death of his uncle in London, whom he had assisted in practice, Dr Craddock set up practice at Shepton Mallet, but removed to Bath in 1882. In November of that year he was appointed medical officer of the Bath Workhouse and held that post for over thirty-one years, during which a number of reforms in the nursing and other services were introduced at his instigation. After serving as deputy coroner for South-East Somerset for five years he was appointed coroner for North Somerset in 1867, and continued to hold that office until his retirement last year. In the course of sixty-two years more than 6,000 inquests were held by him. Dr Craddock was an ex-president of the Bath Pathological Society, and consulting surgeon to the Shepton Mallet Hospital, and for many years was a member of the British Medical Association.

Dr SIDNEY JOSIAH STUCK, who died on October 31st, aged 56, received his medical education at the Middlesex Hospital, he obtained the diplomas M.R.C.S., L.R.C.P., and L.S.A. in 1893, and the M.D. Brux. degree in 1896. He then became house surgeon at Ryde Hospital and afterwards resident medical officer to the Chelsea Hospital for Women. Entering the Whitechapel Infirmary as assistant medical officer, he developed a high degree of operative skill and became a skilful anaesthetist. In 1900 he joined Dr F. B. Hastings in practice in Bow. In 1907 he moved to Leytonstone, the partnership continuing until 1921, from which date until his death he practised alone. His former colleague writes of Dr Stuck that he was most industrious and conscientious, his judgement was sound

and his kindness won the affection, as his skill won the confidence, of his patients. His early and unexpected death is mourned by all who knew him.

We regret to announce the death of Dr GEORGE REIN, consultant medical officer of health for Staffordshire. We hope to publish a biographical notice in an early issue.

Medical News.

THE next session of the General Medical Council will commence on Tuesday, November 24th when the President, Sir Donald MacAllister, Bt., K.C.B., M.D., will take the chair at 2 p.m. and give an address. The Council will continue to sit from day to day until its business is finished.

THE following members of the medical profession are among the majors elected in England and Wales on November 9th: Dr H. J. Campbell (Dartmouth) re-elected; Dr J. C. Dixey (Barnstaple); Dr E. A. Gregg (St Pancras); Dr W. R. Jones (Bristol); Dr R. W. Pearson, M.C. (Arunclay); Dr J. Welsh (Chester).

As announced in our advertisement columns, all applications for 1926 for participation in the Government grant for scientific investigations must be received at the offices of the Royal Society by January 1st, 1926. Applications must be made on printed forms to be obtained from the Clerk to the Government Grants Committee, Royal Society, Burlington House, London, W.1.

THE annual dinner of the Royal Society of Medicine will be held on Thursday next, November 19th, at the Hotel Victoria at 7.45 p.m. The Minister of Health will be the chief guest. Fellows are welcome to invite guests, ladies or gentlemen who can be accommodated at separate tables, if they will notify the senior honorary secretary immediately.

THE annual dinner of the London (Royal Lico Hospital) School of Medicine for Women will be held at the Savoy Hotel, Strand, W.C., on Thursday, December 3rd, at 7.30 p.m.

SIR H. H. PRINCE OF WALLS has graciously consented, as President of the National Association for the Prevention of Tuberculosis, to take the chair at a dinner in aid of its funds on Wednesday, December 9th.

THE Glasgow University Club, London, will dine at the Trocadero Restaurant, Piccadilly, on the evening of Friday, December 4th, when the Right Hon. Sir Henry Galk, K.C.B., LL.D., M.P., will preside. Any Glasgow University men, who, though not members of the club, would like to attend, are asked to communicate with the Honorary Secretaries, 1, Harley Place, N.W.1.

THE next quarterly meeting of the Royal Medical Psychological Association will be held at 11, Chandos Street, Cavendish Square, W.1, on Tuesday, November 17th, at 2.30 p.m. The president, Sir Frederick Mott, will be in the chair, and Dr Garwood will open a discussion on insanity and crime, and will deal with some suggestions arising out of the report of Lord Justice Atkin's Committee. To commemorate the fact that the King has granted permission to use the prefix "Royal" in the title of the association, an informal dinner will be held on the evening of the same day.

A MEETING of the Fever Group of the Society of Medical Officers of Health will be held at 1, Upper Montague Street, W.C.1, on November 27th, at 3 p.m., when Dis O'Brien and Okell will contribute a paper on the Dick test.

ON November 16th, at 5.30 p.m., Sir Henry Gauvain will lecture for the Fellowship of Medicine on the light treatment of surgical tuberculosis, in the lecture hall of the Medical Society of London, 11, Chandos Street, this lecture is open to all members of the medical profession. The West End Hospital for Nervous Diseases will hold a three weeks' course from November 23rd dealing with the diagnosis and treatment of nervous diseases. From November 23rd to December 12th the Royal Waterloo Hospital will hold a course in medicine, surgery, and gynaecology. For the convenience of the general practitioner the London Temperance Hospital has arranged a late afternoon course (4.30 to 6) in general medicine, surgery, and the specialties from November 23rd to December 4th. There will be a special course at the Infants Hospital from November 30th to December 13th. For December the following special courses have been arranged: dermatology (December 7th to 19th) at the Blackfriars Skin Hospital, and a similar afternoon course (4.30 to 6.30) at the Hampstead General Hospital from December 7th to 19th. A copy of each syllabus and the Fellowship general course programme will be forwarded on application to the secretary of the Fellowship, 1, Whitpole Street, W.1.

DR T WATTS EDEN will deliver the David Lloyd Roberts Lecture at St Mary's Hospitals, Whitworth Street, Manchester, on Tuesday, November 17th, at 4 15 p.m., the subject selected is "What we can do for the unborn child."

At the meeting of the Chelsea Clinical Society at St George's Hospital at 8 30 p.m., on November 17th, there will be a discussion on insulin treatment. Drs E P Poniton, George Graham, P J Cammidge, and T G Crookshank will take part.

THE Benjamin Waid Richardson Memorial Lecture before the Model Abattoir Society will be delivered this year by Dr William J Howarth, CBE, medical officer of health, City of London, on the slaughtering of animals for human consumption. The lecture will be given at the honso of the Royal Society of Medicine, 1, Wimpole Street, on Friday, November 20th, at 5 30 p.m. Admission is free without tickets.

At the meeting of the Tuberculosis Society on Friday, November 20th, at 8 p.m., at 1, Upp Russell Square, Dr A Sandison, of the will read a paper on Swiss sanatorium standpoint.

At the meeting of the Central Midwives Board for England and Wales, held on November 5th, with Sir Francis Champneys, Bt, M.D., in the chair, the report on the work of the Board for the year ending March 31st, 1925, was considered, signed by the chairman, and directed to be forwarded to the Ministry of Health. Dr Gerald F Keatinge was approved as a lecturer.

THE National Council for the Unmarried Mother and Her Child will hold an informal conference on Friday, November 27th, at 2 30 p.m., at Carnegie House, 117, Piccadilly, W 1, to discuss the reasons for the disproportionately high death rate among illegitimate children, and the methods of co-operation by which it might be decreased. Professional and voluntary workers interested in this matter will be admitted on presentation of visiting card.

THE disinfection of ships will be the subject of a discussion at a meeting in Plymouth of the Royal Sanitary Institute on Saturday, November 28th, at 10 a.m. The discussion will be opened by Dr G A Borthwick, Port Medical Officer. On the evening of the previous day Dr A T Nankivell, M.O.H. Plymouth, will speak on some points in public health propaganda. Free particulars can be obtained from him.

THE KING on the occasion of the Prince of Wales's return from his visit to Africa and South America, has appointed Surgeon Commander Henry E Y White, M.V.O., R.N., to be an Officer of the Civil Division of the Order of the British Empire.

DR A N BOYCOTT, on the occasion of his retirement as medical superintendent of the Hants County Mental Hospital, Hill End, has been entertained by the staff and presented with a set of table silver.

DR JOHN DYNE, barrister at law, has been appointed colonel for the city of Hull.

CALDECOTE HALL, Nuncaton, organized as a home for cures of certain types of functional nervous disorders, will be formally opened by the Rt Hon Sir William Johnson Parnell, Bt, Secretary of State for Home Affairs, on Tuesday, December 8th, at 1 o'clock. Invitations for the ceremony have been sent out in the name of the Bishop of London and the Central Council of the Church of England Temperance Society. The premises will be open for inspection during the day from 11 till 5 o'clock.

THE first number of *Medicina e Pharmacia*, a monthly journal printed in Portuguese, has been published at Rio de Janeiro under the editorship of Dr Joige de Medeiros e Albuquerque. The issue contains articles by Professor Renato de Souza Lopes on infection in gastro-intestinal ulcers, orthopaedic resection of the knee joint for ankylosis by Professor Figueiredo Brena, the choice of routes for administration of opotherapeutic drugs by Dr Carlos de Silva Arango, and an answer to Pirie by the editor.

IN connection with the present interest in improving post-graduate work in this country it is interesting to note that the Sun Life Assurance Company of Canada has offered to provide 30,000 dollars for the first year's working expenses of inaugurating throughout the Dominion a post-graduate lecture course similar to that arranged in the province of Ontario. It is announced in the *Canadian Medical Association Journal* for August that the offer was gratefully accepted by the association. It will be remembered that on September 26th 1925 (p. 583), we referred to the good work of the Health Service Bureau of the Wesleyan and General Insurance Society, Birmingham, in preparing and distributing health literature and in proposing to make periodical health surveys. These new developments on the part of insurance societies are gratifying indications of their interest in preventive and scientific medicine.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal* should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are
EDITOR of the *British Medical Journal*, **Astology Westcent, London**.

FINANCIAL SECRETARY AND BUSINESS MANAGER
(Advertisements etc) **Articulate Westcent, London**.

MEDICAL SECRETARY **Medicaria Westcent, London**.

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegrams **Bacillus Dublin** telephone 4737 Dublin) and of the Scottish Office 6 Drumshigh Gardens, Edinburgh (telegrams **Associate, Edinburgh** telephone 4361 Central).

QUERIES AND ANSWERS

"Q" asks for suggestions in the treatment of asthma in a young married lady. The condition has existed for some years. The skin reactions are negative. Leptone has been given intravenously and later intramuscularly with temporary relief. The attacks invariably begin between 1 and 3 a.m. and last for hours. The use of an air pillow brings temporary relief. The patient takes nothing to eat after 5 p.m. and is normal in every other respect. The bowels are regular and there is no nasal obstruction.

CRACKED NIPPLES

MEDICALS asks for advice as to the best treatment both prophylactic and curative for cracked nipples. When possible he advises women to keep the nipples scrupulously clean during pregnancy and during the last two months to apply equal parts of castor oil and water daily. If a crack appears he has been accustomed to paint it with frills but would like such precautions as the use of a nipple shield and the application at intervals of hot dipped in saturated borax solution.

MILK STOOLS

DR D W MACDONALD (Ainslie, Westmorland) writes in reply to L.G.'s query (October 31st, p. 822). I have seen excellent results follow the administration of powdered linseed oil. A teaspoonful mixed with marmalade or jam is given each morning, an hour before food. No water or fluid should be swallowed with the marmalade or jam after taking it. When the marmalade persists a second dose may be given (with similar directions) during the day. No special dietary is invoked. The bowels open regularly, with built-up motions.

INCOME TAX

Depreciation of Car

"D W M." has been informed by the local inspector of taxes that he can have an allowance for depreciation of his car but in that case as a change in the method of the allowance is involved the amounts deducted in previous years for cost of replacement of the old car cannot be allowed.

"We are unable to agree with the inspector's view. The cost of replacement was actually incurred and as it seems to us, is clearly allowable especially as no depreciation allowance was ever given in respect of that car. Equally the depreciation allowance is due by statute in respect of the new car. The point has been discussed between inspectors of taxes and other correspondents of this *Journal* and we suggest that D W M. might ask the inspector concerned to reconsider the question and, in the event of his adhering to his view, place the facts before the Secretary, Inland Revenue, Somerset House, London, in writing."

Allowance for Obsolescence of Plant

"D S." inquires as to what allowance can be claimed for the loss incurred through rays and other apparatus being set aside, although not worn out in favour of more up-to-date appliances.

On the value of the whole of the professional apparatus, whether in actual use or not, D S. is entitled to a percentage allowance under the 1925 Finance Act in respect of diminished value by reason of wear and tear, the value should be taken as at the end of the last professional year—**FRY**.

December 31st, 1924—and the allowance operates as a deduction from the assessment (on the usual average basis) for the financial year—that is 1925-26. The obsolescence allowance operates as an allowable expense incurred in the professional year in which the disused apparatus is sold or otherwise disposed of, provided it has then been replaced, and is calculated at the cost price (£x), less the sale price (£y), and less the amount of depreciation allowed for income tax purposes on the particular apparatus (£z). When the obsolescence allowance is made, the latter amount (£x - (£y) + (£z)) should be deducted from the capital value of the plant, etc., for the calculation of future depreciation allowances.

Three Years' Average

"WEST HERTS" has for many years paid tax on his income "year by year" (presumably on the basis of the previous year's earnings), his income has been falling, and the authorities have now assessed him on the average of the past three years. Is this correct?

* Yes, there are certain circumstances in which relief from the three years' average can be obtained—for example, when the income falls off owing to some specific cause, such as may follow on a succession to the practice—but not on the ground that there is an annual reduction, although the result may be that the taxpayer is adversely affected.

LETTERS, NOTES, ETC.

For the benefit of correspondents who have been asking about the rubber boots and shoes recommended by Dr J Fletcher in his letter on the prevention of rheumatism and influenza (October 31st, p 819), he asks us to state that they are procurable from Messrs Foster Bros, Midland Works, Ashbourne, Derby.

A LARGE VERGICAL CALCULUS

Dr J N TURNBULL (Corbridge, Northumberland) writes with reference to the large vesical calculus described (October 31st, p 822) by Dr W A Young of the Gold Coast Medical Research Institute, to say that had Dr Young worked in South Arabia the calculus might have seemed to him quite average. "During my last term at Sheikh Othman, Aden," Dr Turnbull continues, "I removed suprapubically several large stones, mainly from Arabs from the interior, my largest specimen weighed 12 oz/avoirdupois. Unfortunately I have no record available of its dimensions, but they were considerably greater than those recorded by Dr Young. So large as this stone was it is quite possible that the veteran Dr J C Young, who was my senior colleague at Aden, has removed a larger."

MIXED MIA

Dr T M ALISON (Newcastle upon Tyne) writes. With reference to Dr L. L. Fox's letter (October 24th, p 768) I well remember the two letters of Dr Hector Mackenzie and Dr Fox appearing in 1892 in the same issue on the subject of the oral administration of thyroid gland. I was engaged in doing the same thing myself, and had told my colleagues at the Newcastle Dispensary of the good results, and on going to the dispensary on October 29th, 1892, one colleague said, "You are too late, there are two letters in to-day's B.M.J." I quite agreed with Dr Fox that the credit of oral administration should justly be given to Englishmen and not to Denmark. I embodied my own work in my M.D. thesis on myxoedema. One result I obtained was that cooking did not impair the efficacy of the glands, as one of my cases in 1892 obtained the glands from his butcher and took them cooked for breakfast, with good results. If the tablets of thyroids were sterilized by heat they would, I think, keep better and act equally well. Since then I have always given scrums and some vaccines by the mouth, and I think the results are equally as satisfactory as in the case of the thyroid gland.

DIPHTHERIA AND SMALL POX

Dr J READIE SALMOND (Apploby Magna, near Mergham, Burton on Penty) writes—The following case may be of interest. In April last I was called to see a girl aged 9. She was complaining of a sore throat and her mother said she was "taking nothing." I found a typical diphtheritic membrane covering the right tonsil. I took swabs (and had a report later: Klebsiella, bacilli present in large numbers) and injected an initial dose of 8,000 units of antitoxin. The patient was isolated. On the ninth day after injection I received an urgent message to see the patient as she had "broken out all over her." I found her covered with a typical small pox rash. She was seen by the medical officer of health and the county medical officer, who confirmed my diagnosis and she was removed to the county small pox hospital. The father and mother and two brothers were at once successfully vaccinated. Other contacts were traced and vaccinated and the patient made a good recovery, no further cases arising. Save for three pox marks on the forehead the child is very well, the appearance of the small pox rash at the time when one would be expecting a scarum rash might have led to confusion as to the etiology.

GENERAL PRACTICE TO DAY

"JUNIOR G.P." writes. Several years ago I attended some 200 midwifery cases a year, now I do not deliver more than 100. The birth rate may be falling but I think that most of those

cases are sniped by the midwives who, supported by the county council, have undertaken. If the midwife takes out normal cases does it not stand to reason that she should be properly remunerated for attending the abnormal ones who cannot manage? Our training is costly. Last week, at 3 a.m., I responded to a midwife's order—namely, adherent placenta. A general anesthetic was necessary, and the case required several subsequent visits and medicines. For this the county council pays £1 1s, for abnormal labour it pays £2 2s, which is totally inadequate. Do the present day general practitioners realize that private practice is practically slipping away and that we as a class will soon cease to exist? Tuberculous officers visit and treat tuberculous cases, the M.O. often visits and deals with infectious cases, the public vaccinator does vaccinations free, the children attend the school clinics, ante-natal work is taken from us, and venereal cases are provided for. Has the public no sense of independence and responsibility? Must the State provide everything? Again, all middle-class operations and accidents go to hospital and are treated free. The work of the honorary medical staff increases daily, notwithstanding general practice. Can nothing be done to retrieve our position? We have brought this upon ourselves by our apathy and good nature.

INCIDENCE OF OPERATIONS

Dr D. M. OGDEN (London, S.E.) writes to suggest that hospitals should give their patients a card with a brief account in medical language, of any major surgical procedure undergone there which the patient could be instructed to keep carefully and show to any doctor who subsequently attends him or her. "My own experience, and that of many others with whom I have discussed the matter, affords a number of instances of laparotomies that would never have been undertaken had the surgeon been in possession of all the facts precedent. It will be contended perhaps that the patients would lose their minds or that they would by reading them learn what had been done and misinterpret it with the aid of a dictionary, subsequently developing hypochondriacal symptoms. But the proportion of patients whose relatives and friends would permit them to lose so important a document must be very small, while neurotic persons likely to dwell on the subject hardly would hardly be in worse case for having the truth to go upon instead of their own imperfect and exaggerated recollection of a subject which they have not the knowledge to evaluate correctly."

MICROSCOPIC 220

Dr BRIAN B. SHARP (London, W.) writes—On bottles of this dye, as supplied by Messrs Martindale of 10 New Cavendish Street, W., appears a label bearing the inscription "Note particularly error in American literature suggesting 25 per cent solution in gonorrhoea. Strength should not exceed 25 per cent." This statement is misleading. A 25 per cent solution of mercuric chromo 220 can be used with perfect safety and with benefit for application to the mucous membrane of the vagina in children on gonorrhoeal vulvovaginitis. In the treatment of these cases at the Hospital for Ormond Street, the application being made twice a week, and I have never seen any ill effect therefrom. To ensure the thorough painting of the whole of the vaginal wall, and especially the fornices, the application is made through an all distraction in microscope, as described and designed by Colonel Harrison at St Thomas's Hospital. A 25 per cent solution of mercuric chromo is also useful as an application to the cervical canal in women with gonorrhoeal cervicitis. Thus I agree with the above warning only in so far as it applies to the urethra.

"ROAD WISDOM"

UNDER the title *Road Wisdom* the Anglo-American Oil Company has issued in booklet form a series of little notes on the use and abuse of roads. Each of these notes is illustrated with a coloured diagram or drawing. A few simple signals and depicted hints are given on the avoidance of dangers, such as "cutting in," and on taking care at corners and crossings, and on roads under repair. There are illustrations of various "tram track trucks." In several notes the motorist is reminded of sundry courtesies of the road. The up-to-dateness of the booklet is shown by the page devoted to the "white line," and by that which describes and depicts the operation of the "off-side rule," which has recently been approved and advocated by the Automobile Association. Readers of the *BRITISH MEDICAL JOURNAL* may be reminded that the suggestion of this rule was first made by a medical man, and that it has been discussed in our columns on several occasions. The illustration given in *Road Wisdom* shows how well the author has appreciated this excellent solution of precedence and responsibility in traffic. The latter half of the booklet contains short signed articles on the use of various parts of the car on gears, gear changing, driving in traffic, and on some of the rights of motorists. A copy of the work can be obtained on application to the proprietors, *Pratt's Motor Spirit*, 36, Queen Anne's Gate, London, S.W.1.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 39, 40, 41, 42, 43 and 46 of our advertisement columns and advertisements as to professorships, assistantships, and locum tenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at pages 175 and 176.

The Lloyd Roberts Lecture

OR

THE NATURE OF MAN'S STRUCTURAL IMPERFECTIONS.

GIVEN TO THE ROYAL SOCIETY OF MEDICINE,
NOVEMBER 16TH, 1925,

BY

SIR ARTHUR KEITH, M.D., LL.D., F.R.S.

BETWEEN the activities of Archdeacon Paley and those of Elie Metchnikoff lies the greater part of the nineteenth century. At the beginning of this century we find the Archdeacon extolling the perfections of the human body—just as Celsus had done sixteen centuries before him¹. By the close of the nineteenth century the alert and fearless brain of Elie Metchnikoff had discovered, or he believed he had discovered, that the human body was blemished by many imperfections. The evangelist of this new and startling doctrine approached the study of man's body by an untrodden pathway, one made possible by the advancing science of his day. On his arrival at the Institut Pasteur in 1888, being then 43 years of age, he set himself to investigate the means by which the human body combats and keeps at bay such swarming hosts of micro-organisms as find a natural habitat in its internal passages and recesses. He saw man's body as a battlefield—the scene of a perpetual warfare, and as his investigations proceeded the conviction grew on him that the chances of the body's success were imperilled by a heritage of structures which had become out of date and useless. In the Wild Lecture given before the Literary and Philosophical Society of Manchester, on April 22nd, 1901, he declared that man "was being killed by his intestinal flora," and that his great intestine had not only become useless, but was a positive and continual menace to the rest of his body. He believed that the stomach itself, and also part of the small intestine, could be dispensed with. Early in 1903 appeared *Etudes sur la Nature Humaine*,² in which Metchnikoff greatly extended the list of man's structural imperfections.

Between the times of Paley and of Metchnikoff lie three great discoveries, and we must take note of them if we are to understand how it was possible for the one to praise the perfection of man's structure at the beginning of the nineteenth century and the other to

at the end. There was first the discovery that man's body was an aggregate or society of living microscopical units, it was Metchnikoff's fortune to approach the study of man's highly complex body through the simpler societies represented by the bodies of the lower invertebrates, it was thus he came by his discovery that certain units of such societies retain their freedom, thus permitting them to serve as scavengers or phagocytes.

In the second place there was Darwin's discovery, Metchnikoff was a convinced evolutionist. He therefore presumed that the alimentary outfit which served in an anthropoid phase of human evolution must be ill adapted to deal with the dietary of civilized man.

There was in the third place Pasteur's discovery, and so far as Metchnikoff's outlook was concerned this was the most potent of the three. It was under the influence of Pasteur's discoveries that Metchnikoff came to think that the destiny of man lay in the issue of the everlasting contest which went on between the living tissues of the body and the invading hosts of micro-organisms which threatened them.

It is noteworthy that of the three men—Darwin, Pasteur, and Metchnikoff—who revolutionized in the nineteenth century our conception of man's body, and of the struggles to which it is subjected, not one of them was a professed anatomist, the anatomist stood too near to the subject of his study to see it in its true perspective.

Twenty-two years have come and gone since Metchnikoff's

studies on *La Nature Humaine** first appeared, and I propose in this lecture to ascertain how far his doctrines of man's structural imperfections and functional disharmonies have stood the test of time. His thesis presumed that Darwin's theory of man's origin was true, that presumption has been supported by every discovery of the present century, and such evidence as we now have justifies us in believing that the rate of man's evolution has been more rapid than has hitherto been supposed.³

We realize to-day, more precisely than was possible when Metchnikoff wrote, that the most critical chapter in man's long history opened with the discovery of agriculture—a discovery of but yesterday if we reckon time on a geological scale. Agriculture revolutionized the conditions of human life, it made modern civilization possible. We have reason to believe that this revolution in the condition of man's life was initiated either in Mesopotamia, Egypt, or adjacent lands, not more than 8,000 years ago. It is certainly not more than 5,000 years ago, since agriculture began to be practised in Western Europe. The vast majority of the people of these islands, probably 90 per cent of them, are the descendants of men and women who, two hundred generations ago, were dependent on the natural but precarious harvest which is provided by shore, river, forest, and moorland. City life is a new experiment for Europeans, most of us who live in London, if we could go back twenty generations, would find an ancestry which was living on the soil and of the soil. And now the poorest of us can add to our dietary produce brought from the ends of the earth. The alimentary system which was evolved to meet the needs of our primitive ancestors has now to accommodate itself to a modern dietary.

Beyond a doubt civilization is submitting the human body to a vast and critical experiment. It is not only the alimentary system which is being subjected to new conditions—the bony and muscular framework of our bodies is being subjected to novel stresses. Of the present manhood of Britain one-half earns its bread by muscular labour, the other half lives sedentary lives. Our forefathers, when they arrived in Western Europe, were hunters, then bodies were unaccustomed to either manual labour or an indoor life, under the stress of civilization the hunter's body has to serve modern needs. It says much for the adaptability of the human body that it stands these stresses so well as it does. Dr J. D. Cornic,⁴ on examining 10,000 recruits for the army, found that 363 of them suffered from hernia and 113 from flat-foot. Such breakdowns in the supporting system of the body do not occur with this frequency among hunting peoples. Civilization has laid upon some of the weak points in the human body, but the conditions which have provoked them are not of Nature's ordaining but of man's choosing.

If modern civilization is making new demands on our bones, muscles, and nerve controls, it is otherwise with another important system of our bodies. As our manner of living increases in comfort the calls on our heat-regulating mechanism become fewer in number and less urgent in character. Our primitive forefathers lived in the open, their bodies, unhoused and scantily clad, were exposed to sun, rain, wind, and storm. Such a mode of life throws an increasing burden on the machinery which regulates body temperature—on skin on respiratory mucous membrane, and on that elaborate system of reflexes which control the rate of internal combustion. Modern civilization, so far as temperature is concerned, tends to make the human body a hot-house plant.

Metchnikoff perceived that civilization had plunged man's body into a new environment and that the rate of its progress had far outstripped the power of adaptational response which had carried man so far beyond the anthropoid stage. A belief grew within him—almost a grudge—that Nature was letting man down. He brought against the evolutionary powers which preside over the destiny

* In 1907 Metchnikoff published a further work of which an English translation appeared in the same year, edited by Dr P. Chalmers Mitchell under the title *The Prolongation of Life*. In this Metchnikoff replied to his critics and produced more evidence in support of his thesis. Sir W. Arbuthnot Lane formed the opinion that the great intestine was a useless and dangerous structure independent of Metchnikoff's so-called Professor Harold Smith (see an article on the nature of the caecum and appendix in the present lecturer in the BRITISH MEDICAL JOURNAL, 1912, vol. ii, p. 1533).

of man both sins of omission and sins of commission. We shall deal with a sample of each.

The first complaint on his list of omissions is that we have not shed from our skins the last remnants of an anthropoid pelage, hair on the body, he held, was useless and a source of disease. Whether or not a completely hairless body is desirable we may leave as a moot point, a hairless breed of dogs has been produced, and no doubt a hairless race of man could be evolved. In this matter the Chinese has been outstripped by the negro and by the Mongol, the most hairless of races.

It is more to the point to inquire how man has come by a comparatively hairless skin, and in the solution of this problem we have been making some advances. A hairless condition became possible with the evolution of the higher vertebrates, a foetus in the womb draws its heat from the mother's body, it has no need of a hairy covering until the period of birth arrives. There is in the Museum of the Royal College of Surgeons of England a chimpanzee foetus in the eighth month of development, the hair of its head and body has reached a stage identical with that of a newly born child. A stage of development which is over in us. We have come by a new character through the inheritance of one evolved in foetal life. Many of our structural features have come to us in this way. The base of the human skull is greatly flexed. In the foetal stage of all mammals the basi cranial axis is bent, but in man only has this character been carried into adult years. Foetal inheritance becomes more and more possible for man because civilization tends to make man's world into a protective womb.

As an instance of a sin of commission, the introduction of a new and useless structure to the human body, Metchnikoff cites the case of the hymen. It is scarcely time to describe, as he does, the hymen as a new structure, it is present at a certain stage in the embryonic life of every higher mammal, it is only in the human species that it persists and forms a definite and substantial structure in the fully formed body. The hymen provides another example of the human body coming by a new character by retaining and modifying a structure which made its first appearance during embryonic or foetal life. When we seek to explain its use we must enter the parlours of psychology, for around man's sense of sex has grown up a strange hinterland in his subconscious mind. Metchnikoff described the hymen as "an unpleasant impediment", but love, as the world has long recognized, thrives on impediments. The human prepuce, although not a new structure, was, in Metchnikoff's opinion, a useless and dangerous one, circumcision in one generation does not diminish the completeness of its development in the next. In this the prepuce resembles the hymen. Indeed, Metchnikoff said of the latter structure that the only purpose it had ever served was "the overthrow of the dogma of the inheritance of acquired characters".

The examples of the failure of man's body to adapt itself to present requirements which I have cited above are of little more than academic interest, but when Metchnikoff applied his analytical genius to the problems of man's alimentary system he carried us into the realms where thought becomes the guide to action.

It would be no longer rash to say " (so he wrote in 1903) that not only the rudimentary appendix and the caecum, but the whole of the human large intestine is superfluous, and that their removal would be attended with happy results.

Since Metchnikoff penned this sentence the operation of complete colectomy has been performed on many thousands of men and women, but I do not think that even the surgeons who have performed this operation most frequently and most successfully would maintain that a man or woman who has been rendered colonless enjoys that moderate share of health which falls to the average intact individual. If a finger becomes permanently fixed in an awkward position, the hand is improved by the amputation of the offending digit, but the relief thus gained does not restore the hand to its original capacity. The relief afforded by colectomy is of the same kind, the results of that operation in no wise bear out Metchnikoff's doctrine that

the colon has become a superfluous organ in man's body. On the other hand, we have only to consult the pages of the medical press, to listen to tales which reach our ears daily, to note the ever-growing demand for patent purgatives, to be convinced that there is, as Metchnikoff maintained, a grave disharmony between the functional capacities of our great intestine and the dietary which modern civilization has compelled us to adopt. The way out of our difficulties is not to call the colon a useless organ, a "sewage pipe," a "cesspool," but to discover its original purpose and ascertain how far we can modify our mode of living to suit its inherited capacity. What that capacity is we have yet to discover, for we have no complete or exact knowledge of the uses of the great intestine in any animal whatsoever. So far as the human organ is concerned surgery has stepped far in advance of physiology.*

Since Metchnikoff first promulgated his belief that the appendix, caecum, and colon had become superfluous organs in man's body our knowledge concerning the evolution of these structures, and of certain conditions which regulate their action, has increased. That increase of knowledge rehabilitates the ancient belief that Nature in her evolutionary mood exercises not only a surprising ingenuity but also the strictest economy. The ferment and catalysts, elaborated by plants for their own use, were made to serve in the animal body as vitamins. How necessary such substances are for the proper working of the great bowel has been shown by the recent researches of McCarrison⁶ and of Cramer.⁷

It was for the purposes of economy that the great bowel came into existence. In fishes, the earliest vertebrate forms known to us in the living state, potent digestive juices have to be produced at the expense of body tissues, with the evolution of land living, air-breathing forms much of this expenditure was saved by the utilization of bacterial digestion. The great bowel was added to the original intestine for this purpose, the oldest part of this annexe being the caecum and appendix. The great bowel as we know it in fishes is a mere diverticulum from the hinder end of the gut, it takes no part in the digestion of food. Its epithelium forms a glandular structure which has all the appearance of an organ designed for the supply of an internal secretion.⁸ That secretion, whatever it may prove to be, is carried to the liver by the inferior mesenteric vein. In the mucous membrane of the human great bowel there is set embedded in a stratum of reticular tissue (or reticulo endothelium) some 15 million of minute test-tube glands—the glands of Lieberkuhn. No one who has noted the structure and setting of these glands and the finer changes which their cells undergo in the course of action can believe that their sole function is to supply a lubricating fluid for the intestine, they have all the appearance of also supplying an internal secretion, and the evolutionary history of the colon favours such an inference.⁹ The reticular stratum of the colon, which Dr Scott Williamson⁹ regards as the most important constituent of its mucous membrane—and in this I agree with him—represents a spleen of considerable size. Indeed, just as the liver and pancreas represent extrusions of highly specialized parts of the intestinal epithelium, the spleen represents a specialization of the reticulo-endothelium of the alimentary canal in Cyclostomes,¹⁰ the spleen is still intra-intestinal. Nor must we forget how closely the great intestine is linked to the central nervous system—both by afferent and efferent pathways. When we take all these considerations into account we must conclude that the great bowel of man is not a useless or superfluous organ, but one which we, in our ignorance, are maltreating.

Darwin regarded the appendix as one of man's vestigial structures, and Metchnikoff accepted this verdict without demur, although there were then anatomists, particularly Professor R. J. Berry,¹¹ who refused to regard the appendix as a useless structure. Every child is born with a fully and well developed appendix which varies in length round a

* The reader will find a summary of the anatomical evidence relating to the nature of the appendix, caecum, and great bowel by the lecturer in the BRITISH MEDICAL JOURNAL 1912 vol. ii p. 1399.

¹¹ I have not mentioned the excretory function of the colon. This has been investigated by Dr Owen T. Williams. See BRITISH MEDICAL JOURNAL, 1912 vol. ii p. 1281.

mean of 35 mm. Ribbert's investigations¹² showed that amongst the Swiss the appendix has reached its maximum length—97 mm—by the twentieth year, thereafter the average length falls slowly, so that by the sixtieth year it has become reduced to 85 mm. Professor Berry¹³ found in the population of Edinburgh that the appendix did not attain its full length—89 mm—until the fortieth year, falling to 83 mm by the sixtieth year. Drs Garcia and Sillero¹⁴ measured the length of the appendix amongst Filipinos—a people living chiefly on a vegetarian diet. By the twentieth year the appendix of this people had attained a length of 81 mm; its maximum length, 96 mm, was not reached until the fiftieth year, while the average length fell to 82 mm by the seventieth year. An organ which increases in length until the twentieth year, or even until the fiftieth, does not merit the name "vestigial."

The size of the appendix at birth in the various forms of anthropoid apes we do not know, but in adult ghouls, chimpanzees, and orangs, the appendix usually attains a length of 150 or 160 mm—nearly double the length of the human appendix. In the most primitive form of anthropoid known to us, the gibbon, the appendix is most variable in length. In six animals which I dissected fresh from the jungle, all of them adult, the appendix varied in length from 75 to 175 mm. In two of the animals the caecum contained, as part of its contents, numerous fruit stones as large as those of a cherry, the appendix in these two cases held a row of fruit stones showing that it shared in the digestive work of the caecum. There is no evidence to lead us to believe that anthropoid apes suffer from appendicitis in their natural habitat; they become subject to this disease when kept in confinement. Of sixty-one chimpanzees dying in captivity, ten of them suffered from appendicitis.¹⁵ The evidence, such as it is, leads us to believe that when the appendix breaks down under the conditions of modern civilization it does so, not because it is "vestigial," but because of its inability to withstand the conditions to which it is being exposed.

To express the real nature of the structural and functional imperfections seen in the human appendix it is convenient to use a term coined by the late Sir William Gowen. He noted that in some families certain structures, such as the hair on the crown of the head, was apt to be shed as the result of a premature atrophy of the scalp. To such instances of premature senility on the part of any organ or structure he applied the term "abiotrophy."¹⁶ In this sense the appendix is an abiotrophic structure, one which is apt to suffer from a disordered life-history, in a large proportion of Europeans it becomes atrophic or senile when other parts of the body are in full vigour.

On the evidence collected by anatomists and pathologists it is permissible to infer that if we could follow the life-histories of a thousand modern Europeans from birth to their seventieth year the following would be the fate of their appendices. By the end of the tenth year the lumen of this structure would be partially or completely obliterated in 40 of them, by the twentieth year the same fate would have overtaken 70 more, by the thirtieth year 60 others would have been added to the list, by the fortieth year 80 further cases of obliteration would have occurred, by the sixtieth year there would be 110 additional cases. Of the thousand people who reached the age of 70, only 500 of them would retain their appendix in an unblemished functional state, in the other 500 the appendix would have undergone a premature atrophy at succeeding stages in the journey through life. In this the appendix keeps company with all structures which are of a lymphoid nature. The tonsils, the thymus, lymphatic glands, and Peyer's patches have similar life histories, but no one would describe them as vestiges or rudiments. There is much in the name we apply to structures, when we name them "vestigial," "congenital," or "useless," we shut the door on all further inquiry. As Paley declared a century ago, our list of "useless" structures decreases as our stock of knowledge increases.

The eye, which is man's chief organ of sense, has, under the stress of civilization, become the subject of a wrong growth or abiotrophy. If we take a thousand men or

women over the age of 25 we shall find that about 150 of them suffer from a degree of myopia which prevents them from seeing distant objects clearly. And yet in all of them, just as was the case of the appendix, the eye was normal at birth. The incidence of the disorder is somewhat similar to that which befalls the appendix, myopia appears during the period in which the eye is undergoing growth—a process of the most complex kind*, in a few, myopic changes appear by the fifth year, the highest rate of incidence taking place as puberty is reached and passed. We cannot believe that among our hunting ancestors, for whom distant sight was so vital, every seventh man was myopic.

Myopia we must regard as a structural disharmony occasioned by the conditions which civilization has entailed on us. Short sight, as Dr John Kirk has stated,¹⁶ is certainly a disorder of growth and the essential problem is to discover, not why 15 per cent of our population suffer from it, but why it does not occur in the remaining 85 per cent. Children may be fed on the same food and undergo the same school tasks, yet only in certain individuals does the eyeball undergo abnormal elongation. They only are affected by modern conditions, the others are not.

Perhaps no structure in the human body illustrates abiotrophic changes so well as the lens of the eye. By the age of 45 the elasticity of the lens has become so reduced in most of us that we have to seek the aid of spectacles. Some time ago Mr Ernest Clarke¹⁷ examined the eyes of 1,200 people of all ages and charted in graphic form the condition of the lens. From that chart we can see that some individuals at the age of 45 retain the elasticity of lens which is normal to those of 35 years of age, while others have reached a stage usually found in men and women of 60. It is with the lens of the eye as with the appendix—abiotrophy sets in prematurely in some, in others the change is delayed.

The consideration of the functional failure of the lens of the eye brings us to a problem which fascinated Metchnikoff. What is the term of life which was natural to man in his primitive state? Metchnikoff inclined to place it at a hundred years—that if we escaped accident and disease the inherent vitality of our tissues was sufficient to make a centenarian of everyone. At the age of 45 the lens of the normal man is already old, it has reached the term of its full utility. We have no reason to suppose that civilization has shortened or is shortening its period of usefulness. The indication it affords supports the belief that Nature has worked out the evolution of the human family on a mean life tenure of 45 years. She has, until recently, run the human army on a short-service system. Unfortunately we have no vital statistics of our nearest allies, the anthropoid apes. Mickey, a chimpanzee which died lately in the Zoological Gardens, lived there for twenty-six years, and was 3 or 4 years of age when he became an inmate.

Thirty years ago I made an intensive study on the age changes of the teeth and skulls of the great anthropoid apes and came to the conclusion that very few of them reached the fifth decade of life. The elastic tissue and cartilage of our body keeps the lens company in their rate of ageing; they lose their resiliency by the middle of the fifth decade. The age of 45 sees the end of the term of child bearing which is normal for women. When we consult the rates of mortality which now prevail we find that a sudden rise sets in during the fifth decade, and this rise assumes a steeper and steeper gradient with every subsequent decade. All of these facts seem to show that 45 was the span allotted to man when he was the blind slave of Nature. Civilization now permits many men and women to live the span of two such lives, but whether it would be an advantage for civilization that all should live to be centenarians is Metchnikoff believed, is a moot point. We must take civilization in the round, if it has scratched out the weak points in our inherited organization it has also added incalculably to the span and comfort of life.

All the structural imperfections of man's body which have been discussed up to this point are of a kind which perish in the grave. We have no means of telling whether or not

* Subsequently the reader will see that I use this term in a somewhat wider sense—one which includes irregular as well as reduced growth.

I have dealt with the incidence and nature of myopia in the *British Journal of Physiological Optics* 1925 vol. 1 p. 369.

our remote ancestors suffered from appendicitis or were the victims of myopia. Fortunately from this point of view there are certain of the durable parts of man's body which manifest abiotrophic changes—the teeth and jaws. During the last twenty years I have had an opportunity of examining the facial parts of over 300 individuals who lived in England more than a thousand years ago, some of them as much as eight or ten thousand years ago. Seven years ago I made an elaborate comparison between 50 of these ancient skulls—25 of which were adjudged to be those of men and 25 of women—with equal numbers of individuals who had lived in England within the last two centuries.* In only 3 of the 50 ancient skulls did the upper and lower teeth fail to meet in an edge-to-edge bite, in all of the 50 modern skulls the bite was of the overlapping or scissor type. Our teeth are in an abiotrophic state, the failure of the wisdom teeth or third molars to form, or to erupt if they are formed, is but one symptom of this abiotrophic change, it affects crown cusp, and root development. In the 50 ancient skulls, instead of 100 upper wisdom teeth, there were only 82, 13 being absent from non development and 5 from non-eruption. In the 50 modern skulls, instead of 100 upper wisdom teeth, there were only 59, 30 of these were absent from non development, 11 from non eruption.

Such evidence shows that although abiotrophic changes had overtaken the dental system of the Western European as early as the Neolithic period, yet these changes have been accelerated during the more recent centuries. Dental abscesses were nearly as common in the ancient skulls as in the modern, carious teeth, on the other hand, were three times more frequent in modern skulls than in the ancient. The researches of the Mellanbys¹⁴ have proved that the quality of enamel and of dentine, particularly of secondary dentine, has a relation to the vitamin content of a dietary. Equally important for the proper formation of teeth, as McCollum and his colleagues¹⁵ have demonstrated, is the presence in food of a due proportion of certain mineral salts. Nevertheless, although a school of children are exposed equally to unfavourable conditions it is only in a certain number that dental defects will occur, in this respect the dental system behaves as do all structures which are liable to abiotrophic changes.

In not one of the 50 ancient skulls was the palate contracted, whereas in the 50 modern skulls there were 13 in which this condition was present to a recognizable degree—in more than half of them to a marked extent. No matter on which stratum of our population we make observations, we shall find that every fourth or fifth child or adult we examine possesses a palate which, compared with the older type, may be described as both deformed and reduced in size and in shape. I have never seen this defect and irregularity of palatal growth except in skulls from cemeteries of the eighteenth and nineteenth centuries. It may be thought that this irregular growth, with reduction in the size of palate, and the defects in the formation of the jaws and face which usually accompany them, are merely the results of the soft and highly prepared kinds of food we eat, with such a dietary the teeth, jaws, and chewing muscles are deprived of the work which fell to them in more primitive times. That this is not the true explanation is proved by this fact: when children are fed, clothed, and exercised exactly alike all are not affected, only some of them develop irregularities of the palate and jaws. There is a special susceptibility to these imperfections in certain races and in certain families.

Amongst modern British people are to be observed various facial characters, seen particularly in the orbits, in the cheek bones, and in the bony supports of the nose, which are never to be noted in the facial framework of people who lived in Britain during the pre-Nostrum period. When a Continental cartoonist seeks to represent John Bull he always emphasizes these new facial characteristics. Such changes in the form of the facial bones, like contraction of the palate, which they usually accompany, are not the result of a nasal obstruction such as might be caused by enlarged adenoids or tonsils, the cause lies deeper. The incidence of irregularities in the growth of the face follows the same laws as hold for all abiotrophic structures—such as the appendix, the sclerotic coat of the eye, the

thyroid, and the tonsil. Further research will likely prove that the disorders of growth which overtake all of these structures are linked to a disturbed action of lymphocytes and of all the constituent elements of the lymphoid tissues. Dr W. Cramer has become convinced that lymphocytes are actively concerned in assimilation of food and in the nutrition of tissues, and that the nature of the dietary does directly affect their activities. It seems to me very probable that a fuller knowledge of the life-histories of lymphocytes, particularly of the office they perform in growing tissues, will go far to explain the disharmonies which civilization is producing in the bodies of some of us. But the problem of explaining why some members of our community are highly susceptible to these new conditions, while others are less so, and why the majority remain unaffected, will still remain.

I have touched only the fringe of a great subject, I have left undiscussed the numerous imperfections and disharmonies which civilization has made manifest in structures concerned in the maintenance of posture,* and in those which are concerned with the circulation of blood and with the duties of respiration. I have said enough, I believe, to convince you that Metchnikoff was right when he declared that civilization had launched man on a great experiment. From this experiment there is no turning back. We cannot return to the conditions of human life which prevailed in this country six thousand years ago, there are more people in one of the lesser back streets of London than could find an existence in the whole length and breadth of the Thames valley if they returned to the manner of living of our distant ancestors. We cannot go back, we must go on. Seeing how differently we are now circumstanced in every relationship of life—in food, in drink, in shelter, in warmth, in occupation, and in amusement—the wonder is, not that structural imperfections and functional disharmonies should develop in a proportion of our numbers, but that so many of us should escape harm altogether and enjoy good health. It says much for the adaptational reaction which is inherent to the human body that it withstands the artificial conditions of modern civilization as well as it does.

How are our bodies to be protected against these ills with which civilization threatens them? Metchnikoff, a declared and open rebel against Nature, hoped that science might discover some short cut for man's escape, some way of speeding up the evolutionary machinery of his body, and of so making it perfectly fitted for the life which ever advancing civilization is forcing on mankind. I also believe that science will find a means of escape, but not by Metchnikoff's way. The solution of our problem is a fuller knowledge of the use and working of these parts of our bodies which are most apt to give way under our modern ways of living—the use of such structures as the great bowel, and when we have replaced our ignorance by real knowledge we shall then be in a position, not to adapt our bodily structures to our mode of living, but our mode of living to our bodily structures. This seems to me the best way out.

CLOCKWORK CONTROL OF THE CARREL-DAKIN TREATMENT.

BY

CHARLES W. CATHCART, C.B.E., M.B., CH.B.,

F.R.C.S. ENG. AND EDIN.,

CONSULTING SURGEON, ROYAL INFIRMARY, EDINBURGH

AMONG many methods of treating lacerated septic wounds which were tested in the great war the Carrel-Dakin treatment, by intermittent irrigation with solutions of chlorine compounds, proved to be by far the best. Its use saved countless limbs and lives. A nurse, passing from bed to bed, opened a stopcock to allow fluid from a douche can to flow into the distributing tubes and irrigate the wounds. The fluid was released both day and night, every hour in bad cases, and every two hours in less severe cases. The quantities varied with the size of the wound, on the basis of 1 oz. for every three distributing tubes in the wound.

In order to save the labour thus involved, several surgeons suggested the use of siphons, which, when fed slowly, would accumulate fluid and discharge it at definite intervals. I also tried this method, but found it unsatisfactory, because the slow rate of dropping necessary does not continue for more than a few minutes.

The rates of dropping required to supply definite quantities of fluid per hour are easily determined. Since there are 60 minutes in a drachm, and 60 minutes in an hour, the number of drops per minute will yield a corresponding number of drachms per hour. Thus an ounce (8 drachms) per hour would require 8 drops per minute—that is, about 1 drop every 8 seconds. When several different forms of stopcock were tested with pure water (which does not act upon brass) such rates as from 1 to 20 drops per minute steadily decreased in number and soon ceased altogether. A shake of the stopcock would restart them, but they very soon slowed down again and stopped as before. In order to obtain a steady rate of dropping, it was found necessary to begin with about 100 drops a minute—a rate prohibitive for the purpose in view. The use of water with a brass stopcock, moreover, showed that the difficulty does not arise from any corrosive action of the fluid on the metal at the orifice of the stopcock. This behaviour of fluid when made to drop slowly seems to be due to some physical change in the fluid, the nature of which is obscure.

When, as the result of experiment, it seemed impossible to obtain a satisfactory method of intermittent irrigation with a siphon automatically discharged by slow dropping of the fluid, I thought that the desired result might be obtained with a siphon which could be discharged with fluid released, at intervals, by clockwork. This plan, after many experiments, has fortunately proved satisfactory. The clock is used to make and break an electric circuit, which, while closed, actuates an electro-magnet. The magnet, by a simple mechanism (to be afterwards explained), opens a valve and releases quantities of fluid, the amounts of which can be regulated.

The various parts of the apparatus and their relation to one another will be easily understood by an examination of the accompanying illustrations with their explanatory notes.

Fig. 1 shows

(1) The front of the modified clock. The clock face and the hands have been removed, and a light metal wheel has been fixed to the

FIG. 1.

spindle which normally carries the minute hand. A short brass lever A has been screwed into the rim of the wheel. It revolves once in an hour. Other levers could be employed if desired.

(2) Lever 'B'. This carries a vulcanic knob projecting upwards. When this lever is raised high enough by lever A, the knob presses the two adjacent springs together to make a

"contact" and so complete an electric circuit. This in turn, by the action of the electro-magnet lever, raises the piston of the valve and allows fluid to pass (see Fig. 2).

(3) The battery of two dry cells and the ends of the wires which go to, and return from, the electro-magnet. The arrows indicate the direction of the electric current when the circuit is complete (see also Fig. 2).

Fig. 2 shows the essential parts of the stand with its pole 8 ft. high and the frame which it supports. Attached to the frame are

(1) The reservoir, consisting of a 40 oz. bottle, hung upside down, with its mouth within a glass cup, which is attached to the neck of the bottle. (This form of reservoir ensures that the valve is supplied with fluid at a uniform pressure whatever be the level of the fluid in the reservoir itself.)

(2) The small glass siphon and its rubber tube (D), which conveys fluid to the valve when it is opened by the raising of the piston.

(3) The valve. This consists of a small cylinder which has a piston which has a weighted piston rod to make it fall more certainly when released. The upper end of the piston rod is joined to the long arm of the electro-magnet lever by a pin chained to the arm, to prevent the pin from being mislaid. The cylinder is held in position by a thin rod fitting into a socket (not shown). The rod permits of oscillation as the piston is raised. It also holds the valve in its place.

The electro-magnet is of the usual construction. Over the magnets is placed the short arm of a brass lever of the first order, bearing a small piece of steel. When the electric current actuates the magnets they lower the short and raise the long arm and with it the piston rod attached to it. This opens the valve.

The siphon bottle is shown below the valve. The inner end of the curved siphon tube of exit is seen after it has withdrawn a discharge of fluid and passed it into the receiving funnel. The relative levels of the two ends of the siphon tube of exit should be noted.

Four siphon bottles are supplied with their tubes adjusted to deliver
of 1 oz., 2 oz., 3 oz., and 4 oz. of fluid
regulated by the distance, inside the
bottle, of the two tubes from one another.

The quantities delivered by the valve are regulated as follows. The clockwork and electric mechanism has been arranged to hold the valve open for twenty seconds each hour. During these seconds the valve can be adapted to deliver either $\frac{1}{2}$ oz., 1 oz., $1\frac{1}{2}$ oz., or 2 oz., according to the aperture of exit which is given to it. The largest size of aperture is the normal exit. The three successively smaller apertures required can be adapted to the valve by means of three separate nozzles (D), any one of which can be screwed on it will over the aperture of the valve itself. (For convenience, these nozzles are screwed on to the side of the frame which carries the reservoir and siphon, as shown in the figure.)

Generally the hourly quantities selected are allowed to double themselves and be delivered by suitable siphons every two hours. Should the quantities for flushing be required hourly, the larger sizes of aperture may be employed or a second lever "A" may be added to the clock. In every case the siphon which is adapted to deliver the required quantity of fluid must be used (see last paragraph of the description of Fig. 2).

Conduction of the Supplies of Fluid from the Siphon to the Wound

The receiving funnel is used to allow the discharges from the siphon to flow downwards without hindrance from air bells. These, if present, can rise through the fluid in the open funnel, but are held down if the siphon tube is connected directly with the tubes leading into the wound. For a similar reason the tubes leading from the funnel should take the shortest and most vertical route possible to the distributing tubes.

Batteries.—Allow two 1½ volt dry cells for each wound treated. If a number of patients were being treated by irrigation in an accident or military ward it might be advisable to lay an electric circuit round the ward near the floor and supply plugs to tap the circuit at each bed. The strength of the circuit would have to be regulated in accordance with the number of wounds under treatment.

FIG. 2.

From the account now given of the working of this appliance it will be seen that

1 The clock, by its control of an electric circuit, can actuate, hourly or oftener, any required number of electro-magnets for a given number of seconds

2 Each electro magnet can, during that time, open a valve which will deliver more or less fluid to the siphon below it, in accordance with the size of its aperture selected for the particular sound to be treated

3 The required quantities of fluid, when accumulated, can be delivered by the siphon through a tube of sufficient calibre to flush the distributing tubes in the wound

This clockwork controlled douche, which has only recently been completed, has been tested on a severe case of compound fracture of the tibia, infected with *Bacillus pyomyositis*, in Professor John Fraser's ward in the Royal Infirmary, Edinburgh. It irrigated the wound quite satisfactorily. In about a fortnight the wound had improved so much that the clockwork control, being no longer required, was discontinued

There are many septic surfaces and cavities met with in civil practice, from different causes, for which the Carrel-Dakin treatment will be required. It is hoped, therefore, that this appliance will serve a useful purpose for these apart from the possibilities of war wounds, which, unfortunately, cannot yet be excluded from the horizon

In working out the details of this appliance new problems had to be faced and many experiments were necessary. I am much indebted to several co-workers whose services have been invaluable

To Mr Hurford of Messrs Smith Hurford, and Drysdale for adapting the clock for its new purpose and working out the details of the supply valve for me also for devising and making several experimental stopcocks to Mr T. Alexander, the head of the dispensary in the Royal Infirmary, Edinburgh, for testing the action of enamel on metal and keeping me right in chemical questions and very specially, to Mr A. H. Baird, for the electrical outfit and all glass work, and along with him, his ingenious and skilful mechanic Mr George Pringle

The complete outfit will be supplied by Mr A. H. Baird 30 Lothian Street Edinburgh

THE PATHOLOGICAL LABORATORY IN GENERAL PRACTICE.

BY

S. C. DYKE, D.M., M.R.C.P.,

CONSULTING PATHOLOGIST TO THE WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL AND TO THE WALSALL GENERAL HOSPITAL

THE conception of the pathological laboratory which I wish to put forward is that of a centre for the diagnosis and investigation of disease. By diagnosis I do not mean the mere application of a name to a particular morbid condition or syndrome, but a comprehension of the disordered processes underlying any particular set of symptoms. That correct diagnosis is the first step towards efficient treatment—where such exists—will, I suppose, be universally admitted, and it is as an instrument for the achievement of correct diagnosis that I would regard the pathological laboratory of a general hospital. In spite of the accumulation of physiological and pathological knowledge which has marked the last few decades, it must, I fear, be admitted that the points at which actual contact is established between the science and the art are still few. None the less such contacts do exist, and are increasing. The function of the pathologist in the medical community, as I see it, is to familiarize himself with those points of contact and to place the knowledge won by the workers in medicine and the science at the disposal of the workers in medicine.

Of the ways in which recent advances in biochemistry have added to our knowledge of disease one of the most important is the devising of a simple and easy method for the estimation of the sugar in a small sample of blood. Several methods have been worked out within the last few years, the one most generally used in this country is that devised by Professor H. Macleod of St Thomas's Hospital, London.

* An address delivered before the Wolverhampton Division of the British Medical Association.

Which method is used is of no particular importance. The point of importance is that the introduction of this procedure has brought about a better understanding of that group of conditions having the common symptom of glycosuria than was ever before possible.

Time was when the presence of a reducing substance in the urine was always regarded as an ominous symptom. Soon it became recognized that lactose might appear in the urine of pregnant and nursing women without being of any serious prognostic significance, later the occurrence of pentosuria was recognized. When faced with a reducing body in the urine of a patient it is necessary to make sure that that body really is glucose. A fragment of brewer's yeast will, of course, give the answer. The presence of glucose being established, the question demanding an answer is, Is this, or is it not, a "diabetic" condition? The answer is readily afforded by the examination of the blood

To make clear how this answer is given, I must go briefly into the variations of the blood glucose level after the ingestion of carbohydrate by a normal subject. In investigating the rise and fall of the blood sugar after the ingestion of carbohydrate it is obviously desirable that some standard method should be employed. All the curves given below are plotted as suggested by Professor Macleod on the results of blood sugar estimations made after the ingestion of 50 grams of glucose following a fast of at least three hours

The Normal Sugar Curve (Fig 1)

You will note that from a fasting level of about 100 mg per cent the blood sugar rises rapidly to 180 mg per cent. This height is attained in about one hour, after which there is a rapid fall to the original level or just below it, so that in a normal person within one and a half hours the blood sugar is back to where it started from. The two points to which I particularly wish to draw your attention are this rapid fall and the maximum height of the curve. The rapid fall is due to some mechanism for the storage of glucose in the body, the nature of which is not understood, it is apparently the disturbance of this storage mechanism which is the essential lesion in diabetes. The height of the curve is of importance because it represents the level to which the sugar may rise in the blood without passing through the kidney into the urine—that is to say, there is a threshold for glucose in the blood. This threshold occurs at a level of about 180 mg. When below that level in the blood, glucose will not normally appear in the urine, when above, it will.

Fig 1—Normal blood sugar curve. Ordinate=Blood sugar in milligrams from ingestion of 50 grams of glucose by the mouth. T=Normal renal threshold for glucose.

Fig 2—Diabetic blood sugar curve. Abscissae=Time in half hours from the mouth. T=Normal renal threshold for glucose.

The Diabetic Curve

The level of the diabetic curve may vary, but its shape is perfectly characteristic (Fig 2). There is a complete absence of that rapid fall due to the coming into play of the storage mechanism which is characteristic of the normal subject. This, as I have remarked before, is apparently the actual physiological basis of the diabetic condition, the level of the blood sugar rises well above the threshold, and this, of course, accounts for the glycosuria. It may be, and usually is, above the threshold to start with. That is a further very important point in the diabetic condition.

is that the threshold may be raised, this is so frequently the case as to be almost the rule in elderly persons. Thus no sugar may be excreted in the urine until a hyperglycaemia of 300 mg per cent has been established, as opposed to only 180 mg per cent in the normal subject. You will at once perceive from this that the absence of sugar from the urine is no proof of the absence of a hyperglycaemia, and it is the hyperglycaemia which matters.

The importance of the estimation of the blood sugar as an aid in insulin dosage will be apparent to you without further comment on my part. In diabetes it is the level of the blood sugar that matters, the appearance of sugar in the urine is in the nature of an accident, its amount is really neither here nor there, and its disappearance is no indication that the hyperglycaemia is under control.

Before I leave this question I will draw attention to two other forms of glycosuria.

It happens in some cases showing glycosuria that the blood sugar curve shows that the level of the blood glucose rises and falls in a perfectly normal manner. If samples of urine are taken half-hourly throughout the estimation, however, one finds that sugar is passed in the urine when the blood sugar is at its highest level. Careful observation will reveal a definite level below that of the usual threshold at which sugar passes from blood to urine—that is to say, there is a lowering of the threshold for glucose. This condition is compatible with perfect health and requires no treatment. Its recognition, however, is of obvious importance, and this is only made possible by plotting the blood sugar curve.

The "Lag" Curve

A further somewhat rare type of blood sugar curve is the "lag" curve (Fig 3). The essential feature of this curve you will note to be a delay in the coming into play of the storage mechanism. When it does come into play it works as efficiently as in a normal person. The result of this delay is that the blood sugar rises higher than normal and that, consequently, sugar passes into the urine. The significance of this type of curve is as yet doubtful. It appears to be compatible with a rude state of health and requires no treatment, though moderate limitation of carbohydrate in the diet might be advisable.

FIG 3.—Lag type of blood sugar curve.

I will now pass on to the question of the investigation of the state of the kidneys in nephritis and other conditions. To start with, may I point out that under the heading of "nephritis" are included a large number of diverse pathological conditions. Roughly, however, they may all be grouped under three heads: (1) acute nephritis, (2) chronic nephritis, secondary to acute, (3) primary chronic nephritis.

Clinically Group 1 is characterized by oedema and albuminuria. Group 2 in its early stages is characterized by the same symptoms, later, however, if the patient survives, the oedema may disappear and the albuminuria become less. Group 3 in its early stages is characterized by no marked symptoms and is one of the most insidious of all diseases.

Of cases belonging to Group 1, I have, as a result of my own observations, been able to satisfy myself that two types exist. The symptoms of these two types in the early stages are practically identical, but their actual pathological bases are entirely different and the prognoses poles apart. I have been able to demonstrate that in the one type, which, following the German authorities, I may speak of as a nephrosis, there is no evidence of inflammation of the kidney, in the second type the whole renal substance, but particularly the glomeruli, shows evidence of intense inflammation. Clinically in the early stages the two types are indistinguishable—both show oedema and albuminuria, the former may persist for months, the latter for life. But the outlook in the two types is quite different. In the first recovery is the rule, the second

tends to go progressively downhill. The oedema may disappear, but even so chronic interstitial fibrosis progresses in the kidneys, and death ultimately occurs from renal failure.

By examination of sections of the kidney removed during life it would be an easy matter to give a prognosis. I have done this, but do not recommend it as a routine. Fortunately examinations of other sorts are almost as efficacious. These examinations depend upon the ability of the kidneys to excrete urea. In both the types of nephritis of which I have spoken there is during the first week or so a failure on the part of the kidney to excrete urea, but the later course of the two types shows a marked difference in this respect. In the nephrotic type, even when the oedema and albuminuria still persist, the kidneys are soon able to excrete urea as well as those of a normal subject. In the inflammatory type, on the other hand, the power to excrete urea undergoes a progressive impairment, and this substance tends to become backed up in the blood.

By estimations of the blood urea and the power of the kidneys to excrete a dose of urea given by the mouth, as recommended by Maclean and De Wesselow, one can usually gauge in which direction any given case is likely to proceed and gain important information both as to prognosis and treatment.

Consideration of the findings in two typical cases may make the matter clearer. Clinically these cases were of the same hydraemic type, both showing albuminuria and oedema.

Case 1—The facts are contained in the following table

Urine urea before ingestion of 15 grams of urea	17 per cent
1 hour after	27 "
2 hours after	29 "
3 hours after	30 "

Blood urea 30 mg per 100 ccm

Case 2—In this case the results were as follows

Urine urea before taking urea	11 per cent
1 hour after	11 "
2 hours after	12 "
3 hours after	09 "

Blood urea 68 mg

In the first case there is no failure of urea excretion, in the second there is such a failure. In Case 1 the prognosis is good, in Case 2 some degree of recovery may take place, but the ultimate prognosis is poor.

Case 3—A third case indicates the usefulness of this procedure in another direction. It is that of a boy who originally suffered from an attack of acute nephritis. The oedema disappeared but the albuminuria persisted and the boy suffered from bouts of head ache and vomiting. It was plain that these might be renal in origin and he was kept on a strict low protein diet and treated more or less as an invalid. Investigation of the case revealed the following state of affairs:

Urine urea before urea by mouth	17 per cent
1 hour after	21 "
2 hours after	25 "
3 hours after	23 "

Blood urea 35 mg per 100 ccm

Obviously in this case there is no urea retention and therefore no necessity for a low protein diet. The patient was put on a full diet, his parents were told no longer to regard him as an invalid, an error of refraction was corrected by suitable glasses, and as a result the bouts of sickness ceased, and he is now in excellent health in spite of a slight persistent albuminuria.

Nephritis of the last type—the primary chronic interstitial—is essentially a disease of the fourth and fifth decades, but may appear and run its insidious and unchecked course at all ages. Albuminuria and oedema are never marked and are frequently altogether absent. Often the only complaint of the patient is of headache and dizziness. The outcome is always death in uraemia. This is above all the type of nephritis associated with urea retention. The following case is typical.

Case 4—A man aged 42 complained of headache and malaise for some months past. His skin was muddy, he was anaemic and showed pouching under the eyes but no oedema. Examination of the power of disposing of urea yielded the following results:

Urine urea before taking urea	11 per cent
1 hour later	11 "
2 hours later	09 "
3 hours later	05 "

Blood urea 90 mg

Two months later the condition is as follows

Urine urea before taking urea	0.9 per cent
1 hour later	0.9 "
2 hours later	0.8 "
3 hours later	0.75 "

Blood urea 120 mg

After another two months

Urine urea before taking urea	0.65 percent
1 hour after	0.65 "
2 hours after	0.5 "
3 hours after	0.4 "

Blood urea 210 mg

Death took place in a few weeks, with a blood urea of 450 mg per cent

As to treatment, the only point I should like to make is that in cases in which urea is being well excreted there is obviously nothing to be gained by withholding its principal mother substance—the protein of the diet. In fact, in the nephrotic type of case of which I have already spoken definite harm results. Urea is an admirable diuretic, and when it can be excreted its presence in the blood is invaluable in getting rid of oedema. In this type of nephritis not only should the patient be encouraged to take a full protein diet, but urea may with benefit be administered in large quantities by the mouth.

There is one other type of case in which examination of the renal function is of the greatest value, and that is in prostatic enlargement when an operation is contemplated. In these cases, when there has been prolonged obstruction to the urinary outflow, the kidney function as a rule becomes to some extent impaired. The degree of impairment varies and is subject to very great improvement with treatment. In many cases where the prostatic enlargement has persisted for some time examination of the urea concentrating power of the kidney shows definite failure. If prostatectomy is performed while the patient is in this state the results are bad—a fatal issue is common. If, on the other hand, a preliminary cystotomy is performed and the urine is allowed to drain, subsequent tests usually show a progressive improvement of renal function and indicate with comparative certainty when the operation may be completed with safety.

I would not have you think that it is only on the biochemical plane that the pathological laboratory may be of assistance in the diagnosis of renal disease. In all forms of infection of the urinary tract—coccal, coliform, or tuberculous—the ultimate diagnosis must be made by the microscope or culture medium. Here, however, let me point out that although information of the very greatest importance as to the nature of infections of the urinary tract can be gained by an intelligent use of the pathological laboratory, the attainment of those given results depends entirely upon close co-operation between the clinician and the pathologist. There is no more useless specimen than the bottle of urine unaccompanied by details of the case and the mode of collection. For the interpretation of results it is necessary to know something of the history of the case and also of the particular specimen. Often, in order to arrive at a definite result, it is necessary to call in the surgeon to collect specimens from each ureter separately. All this may seem to entail a lot of trouble, but, unfortunately, correct diagnosis is like that. It does entail trouble, in this and in most other instances. On the whole, however, it is worth it. I will cite two instances.

Case 5—A medical man had suffered for two weeks from an irregular pyrexia, with diffuse abdominal pain. The diagnosis however lay between infective endocarditis, typhoid fever, and a grumbling gall bladder. The urine was said to show nothing beyond a trace of albumin. Culture of the blood the Vidal reaction, and various other procedures were without result. Examination of the urine gave an immediate diagnosis of *B. coli* infection of the right kidney.

Case 6—A boy had suffered for many weeks with painful and frequent micturition. The urine showed pus and blood but no organisms. X-rays showed a shadow that might have been a stone in the left ureter. Catheterization of the ureters showed that the pus was coming from the right kidney only. Examination of suitably stained films of this catheter urine showed numerous tubercle bacilli. At operation the right kidney was found to be almost destroyed by a tuberculous infection.

Assistance can be given in many other directions. There is, for example, the examination of the test meal in the differential diagnosis between simple and malignant gastric ulcer. The x-rays will frequently detect the presence of the ulcer but they are powerless to diagnose malignancy

or its absence. The presence of lactic acid and the absence of free hydrochloric acid are almost proof positive of malignancy. The examination of the faeces as to the relative amounts of split and unsplit fat will often throw light upon the nature of obscure diarrhoeas. In such conditions a relative increase of the unsplit fat due to the absence of the pancreatic lipolytic ferment is practically diagnostic of a pancreatic lesion. In the differential diagnosis of jaundice the van den Bergh reaction for the detection of urobilin in the serum is often of the greatest assistance. This reaction appears to depend upon the fact that the urobilin which ultimately finds its way into the bile is not produced in the liver, but in the widespread endothelial reticular system, its source being the haemoglobin of broken-down red cells. When first produced the urobilin is apparently linked to a protein molecule, but becomes separated from it on passage through the liver cells into the bile. When still linked to the protein the urobilin will give no colour reaction with the van den Bergh reagent, the linkage, however, can readily be dissolved by treatment with alcohol, whereupon the reaction occurs. The occurrence of a colour reaction on simply bringing the van den Bergh reagent in contact with the serum constitutes the direct reaction and indicates an obstructive icterus. If, on the other hand, no reaction occurs until the serum has been treated with alcohol, the reaction is spoken of as indirect and indicates that the jaundice is due to pigment that has never passed through the liver. Such reactions occur in those cases of haemolytic jaundice where, presumably owing to rapid blood destruction, so much urobilin is produced that the liver cannot readily dispose of it. It is in the identification of this particular type of icterus that the test has its particular use.

Very valuable information may be provided by the examination of the blood picture in the various anaemias. I can best indicate how important such an examination may be by citing a case.

Case 7—A man presented himself with the statement that he was suffering from leukaemia. His spleen was large reaching to the umbilicus. He was slightly jaundiced and showed ulcers on both legs just above the ankles. He stated that he had been ill for seven years. Examination of the blood showed the following picture:

Red cells	2,500,000 per c mm
White cells	18,300 " "
Haemoglobin	45 per cent
Differential count	
Polymorphs	75 per cent
Lymphocytes	20 "
Monocytes	4 "
Eosinophils	1 "

This is obviously and emphatically not the picture of a leukaemia. Guided by the slight jaundice and the splenomegaly I estimated the fragility of the red cells and found that lysis commenced at a concentration of 6.5 per cent of sodium chloride and was complete at 4 per cent—a very marked increase of fragility. The van den Bergh reaction gave an indirect positive result indicating the haemolytic nature of the jaundice. The whole picture was that of haemolytic or acholic jaundice. The importance of the differential diagnosis here lies in the fact that whereas in leukaemia removal of the spleen is invariably fatal in acholic jaundice it is equally invariably followed by marked improvement. A spleen weighing some 2 lb was removed by Mr E. Darnley, F.R.C.S., and the patient is now doing excellently.

I could cite many other instances of the value of laboratory methods in providing diagnosis and indications as to treatment. In conclusion, however, I should like to lay stress upon a point which I have already mentioned, and that is the absolute necessity for close co-operation between practitioner and pathologist if really useful results are to be attained. With the possible exception of the examination of sputum for tubercle bacilli, I can think of no laboratory procedure used in diagnosis from which the best results can be obtained without some knowledge of clinical details. All results obtained in a laboratory require interpretation in the light of experience and the nature of the individual case. In many instances a few minutes' consultation between practitioner and pathologist over the case may lead to the opening up of fruitful lines of investigation of which neither would have thought alone. In short, to get the best results from a pathological laboratory it is necessary to regard it, not as a slot machine which, on the insertion of a bottle of something and a fee, produces a diagnosis and a bottle of vaccine in return, but as an institution for the practical application of some of the accumulated knowledge and experience of the nature of disease.

British Medical Association.

PROCEEDINGS OF SECTIONS AT THE ANNUAL
MEETING, BATH, 1925

SECTION OF ORTHOPAEDICS.

Professor E W HAY GROVES, M S, F R C S, President

DISCUSSION ON
TUBERCULOUS DISEASE OF THE SPINE

OPENING PAPERS

I—Sir HENRY GAUVAIN, M D, M CHIR,
Medical Superintendent Lord Mayor Tieton Cripples'
Hospital and College

TUBERCULOUS disease of the spine is one of the most common and most serious of all forms of bone and joint tuberculosis. It is therefore particularly appropriate that it should receive the attention of this Section. Untreated or inadequately treated, it is a grave menace to the patient attacked, appropriately treated, few forms of severe bone tuberculosis offer such satisfactory prospects of cure without considerable disability.

Reviewing the years since I started work at Alton, the most striking facts to record are (1) the slow but steady revolution that has taken place in our conceptions of the nature of the treatment to be adopted, (2) the greatly increased and increasing facilities for such treatment by the establishment of specialized county hospitals for the cure of such patients, particularly for children, and also to a lesser extent for adults, (3) research into the etiology of the disease, which has established the fact that a considerable proportion of the cases in children are due to infection by the bovine bacillus, a source of infection which could be prevented, (4) education of the public as to the dangers of infection, means of prevention of infection, and the treatment to be enforced by the propaganda of societies such as the National Association for the Prevention of Tuberculosis and other admirable bodies, (5) co-ordinated work by public health authorities, the appointment of tuberculosis officers and nurses who search out and examine contacts, school medical officers, infant welfare clinics, and the like, the sum total of whose work in limiting infection and ensuring early diagnosis must be considerable, and lastly (6) the combined effect of all these factors in limiting the incidence and ensuring early and efficient treatment of the disease.

Distressing cases of advanced tuberculosis of the spine with severe deformity, from large urban areas, notably London, are not nearly so common as they were a generation ago. Indeed, by the organization existing in London it is possible for infected school children to obtain residential institutional treatment within a week or two after the diagnosis of spinal caries. Naturally, therefore, cases with advanced deformity are becoming increasingly uncommon. I think it is safe to predict that in ten years they will be rare, and in twenty years' time should be almost non-existent. From country districts severe cases are still exceedingly frequent, but it is not improbable that in another twenty years a discussion on the correction of severe deformity following tuberculous disease of the spine will be of mere academic interest—at any rate, it should be if the efforts now inaugurated are continued.

With regard to treatment, I think it may be taken for granted that in the present state of our knowledge conservative treatment, in its widest sense, is the treatment of choice. Spinal caries, like other forms of surgical tuberculosis, is but a manifestation of a general disease, and demands general as well as local treatment. Conservative treatment as undertaken to day may be defined as the adoption of all measures which tend to improve the patient's general health, increase his powers of resistance to tuberculous disease, and preserve or restore the part attacked. It includes consideration of general treatment, involving climatic, hygiene, drug, disciplinary, educa-

tional, and other measures which it is desirable to employ, and of local treatment of the actual spinal lesion, which is concerned with the correction or prevention of deformity and is largely orthopaedic in character, but subject to those limitations enjoined by reason of the fact that the patient is tuberculous. Under this heading may also be included those surgical measures, also conservative, which as yet retain a place in treatment certain of these are still essential.

Further to my remarks about the frequency of bovine infection, there is reason to believe that this is increasing relatively. It is difficult to convince the lay mind that milk, which is admittedly one of the most valuable of foods, may be in the raw state the most dangerous to the health of the child. In young children the percentage of cases of surgical tuberculosis infected from bovine sources is high. The incidence decreases rapidly with advancing age. It would appear that certain bony lesions are more liable to infection from bovine sources than others, and of these the vertebrae are the most frequently attacked. There are reasons for believing that from 30 to 40 per cent of all cases of non-pulmonary tuberculosis in children in England are infected from bovine sources, in Scotland the percentage is even higher. The subjoined table, of certain cases of my own in which the pus was bacteriologically examined by Dr A. Stanley Griffith, shows an incidence of over 60 per cent of cases of spinal caries originating in children under the age of 10 years infected from bovine sources. Above the age of 10 years the incidence of infection from bovine sources very rapidly diminishes.

Analysis of 192 Recent Cases of Surgical Tuberculosis of the Author's

	Under 5			Between 5 and 10			Between 10 and 15			Total Percentage Bovine

The pus from each patient was examined by Dr A. Stanley Griffith for human or bovine tubercle bacilli. (From a paper entitled, 'The extent of damage done by tuberculosis derived from infected milk and methods of prevention,' *Proceedings of Ninth Annual Conference of National Association for Prevention of Tuberculosis*.)

I consider these facts to be of the utmost importance and justify allusion even before a Section concerned with treatment rather than prevention.

I do not propose to deal at all with the question of diagnosis of spinal caries. With modern aids, diagnosis is as a rule easy, at any rate when the disease is fully established and even before marked deformity arises. The chief obstacle to early diagnosis occurs in young children in whom symptoms pointing to disease in the spine have not been discovered by the parents until deformity has developed, or in older patients where referred pain and absence of complete examination has permitted the condition to be overlooked. Perhaps differential diagnosis may be discussed by subsequent speakers, considerations of time prevent me from further alluding to this interesting and essential subject.

Allusion should be made to those methods of treatment which have attracted very considerable attention in recent years and which I shall term adjunct. These include heliotherapy and artificial light treatment, aerotherapy, balneotherapy, vaccine therapy, chemotherapy, x-rays, and other electrical forms of treatment. All these adjunct methods are of extreme interest and often exceedingly helpful, they are never absolutely essential, but are frequently capable of being utilized with advantage at some

on all stages of the disease, alone or in various combinations, and if judiciously employed they may be of much benefit to the patient. Before a Section such as this, while emphasizing the importance of general and adjuvant treatment, and asserting that these should be regarded as almost indispensable aids to cure and certainly utilized to the fullest extent wherever and whenever possible, I deem it more appropriate to confine my remarks to local treatment entirely, as it is this feature in the therapy of spinal caries which is of especial interest to the surgeon and orthopaedist, and is also essential if the best results are to be obtained.

I would first briefly allude to surgical measures in treatment, and would state as a rule, to which there should be few exceptions, that tuberculous abscesses secondary to spinal caries should not be opened. When closed, except in those situations, as within the spinal canal, where from mechanical reasons they may be dangerous, they are comparatively harmless. When incised and drained there is a very real danger of sinus formation and secondary infection. Reliable statistics show that, in general, in cases of spinal caries with septic sinuses, an ultimate direct mortality of some 75 per cent may be anticipated from septic exhaustion or myeloid disease. With the assistance of adjuvant measures this mortality may be reduced, but will always remain high. Neither is it wise to leave tuberculous abscesses to absorb if that is avoidable. While rarely directly dangerous to life, they permit spread of the disease, destroy the tissues with which they come into contact, incite toxicemia, and delay cure. Where these abscesses are accessible, as soon as possible after their formation and as early in their evolution as the skill of the surgeon permits, they should be aspirated. Occasionally then aspiration may be assisted by the employment of modifying fluids. The technique and arguments for the selection of this method of treatment of spinal abscesses Calvé and I have already described.⁴ Given efficient technique, I have no hesitation in

FIG 1—Deformity which had arisen after Albee's operation

advocating this method of treatment of spinal abscesses in preference to all others, and I believe this treatment is now being increasingly favoured. Aspiration may be adopted in even seemingly impossible situations. Thus, with a special trocar and cannula I have been enabled to aspirate retropharyngeal abscesses through the mouth. Such abscesses if drained through the neck are, if deeply situated, difficult of access, and sinuses in this region are often very slow in healing. In cases of paraplegia due to abscess formation within the spinal canal Calvé's aspirates by means of a specially designed trocar and cannula which he introduces through the intervertebral foramen. In unsuccessful cases costo-transversectomy or laminectomy has to be undertaken. Calvé has asked me to express his disapproval of Albee's and Hibbs's operations in spinal caries in children. His view is, I think, now fairly generally accepted, and with it I cordially agree. Such operations have little value in shortening the period of treatment in children, they are by no means devoid of danger, unless prolonged and careful after-care is instituted, they will not prevent the onset of deformity, and, if deformity exists, they will prevent the application of measures calculated to correct the deformity. They will not even ensure against relapse. I have under my care at this moment a patient who, ten years ago, had an Albee operation performed on the lumbar spine. The spinous processes remain ankylosed, but the disease has either recurred in the original lesion or was never quiescent, and the patient has a psoas abscess which has extended under Poupert's ligament. This is interesting in showing that immobilization of the spine may not be sufficient of itself to arrest cures. Another patient on whose spine, then without deformity, Albee's operation was performed came under my care two years later with extreme deformity which could not be corrected (Fig 1).

These operations are of interest, as they are essentially conservative. No attempt is made to deal with the lesion

which calls for such an operation. They are simply an internal method of splinting the spine and a substitute for instrumental skill. In adults bone-grafting of the vertebrae has a field, though it cannot be argued that it is an essential operation. It is attractive, almost dramatic, and doubtless succeeding speakers will testify to its value in selected adult cases, but it behoves us to remember that while it may leave a rigid spine it does not necessarily leave a healed spine, and valuable external evidence of healed tubercle is lost. In children I assert that it is an unnecessary operation, provided reasonable facilities are available for treating the patients, in certain cases it has distinct and considerable dangers. Its great value, to my mind, is that it simply confirms the experience that to immobilize an extensive bony tuberculous lesion is a better way to promote its healing than to attempt its extirpation.

I would appreciate the operation more if it made cure certain where a purely non-operative treatment would have failed, but I cannot conceive that it would have saved the life of any one of my spinal patients who have died. I know it would have increased my mortality if generally adopted, and I think I can demonstrate that it would have made little appreciable difference in the length of treatment required. Therefore I would reserve such operations, which are rarely, if ever, essential, for selected adult

cases. In adults justification may be found for the operation when vertebral destruction is taking place, as in lesions arising within the vertebral bodies, but it should be remembered that in adults the primary lesion commences not infrequently just beneath the anterior common ligament, and the tendency here is for the disease to spread beneath this ligament and not to invade the bodies deeply. In such cases immobilization in plaster is, I think, sufficient. Where adequate conservative treatment will not relieve pressure symptoms, then I think it will be generally agreed

that laminectomy or costo-transversectomy is indispensable, but I need hardly remind you that really adequate conservative treatment should first receive thorough trial. It is surprising, if such treatment is first adopted, how rarely recourse has to be had to operative measures.

I turn now to the consideration of mechanical means of treatment, which aim at the prevention or correction of deformity and are of great interest to us from an orthopaedic standpoint, but, as I would again emphasize, are but a part of the treatment to be adopted. Regarded from this aspect, one may briefly sum up that in early, acute, or progressive cases, three desiderata are called for: (1) dorsal recumbency to ensure rest to the body, (2) immobilization of the part attacked, the spine, to secure rest of the lesion, and (3) as a general rule, and provided extreme deformity has not already developed, hyperextension of the spine to prevent the occurrence of deformity, or to reduce moderate deformity which may have arisen, and to relieve muscular spasm, which, though Nature's way of holding a spine rigid and thus checking movement in the inflamed area, nevertheless often involves the crushing in of inflamed and softened vertebral bodies and the production of deformity. Dorsal recumbency alone is insufficient, hyperextension of the spine is essential if deformity is to be certainly prevented. In an ordinary case of acute caries, provided these essentials are obtained, the method matters but little. Details will be found to differ greatly in the practice of different surgeons, and the various methods applied have their respective advocates. If a surgeon decides on any particular method and his staff is properly trained in its use he will get such good results that he may be inclined to regard his method as superior to the methods adopted by others. My own feeling is that the simpler the appliance employed, the greater the comfort ensured to the patient, and the fewer the complications in the apparatus, the better the result will be.

I have tried every method I have heard of, and have come to the conclusion that the simple spinal board, with jacket, mattress, and hyperextension applied as required, and as used at Beck, is the best for all round treatment in straightforward cases. It meets every essential, it is clean and hygienic, it is comfortable, and it is effective. The but unless this is specially arms and legs may be moved, contained there is no objection to this and the patient's comfort is increased. If it is desirable to keep the legs still they may easily be strapped. Further and no refinements in the simple early case are of no commensurate value. It is again the story of common sense in treatment—the man, not the machine. In a hospital especially such a standard apparatus is particularly useful. Its fittings are standardized—a great convenience for stock and laundry. It is available for every case and may be adapted to meet every need. Nevertheless, for particular phases of the disease

more elaborate apparatus is often required if the best results are sought for. With paraplegia it is often desirable to add head and leg extension, with at times some degree of hyperextension. If there is deformity with much muscular spasm it is advisable first to flex the spine until the compensatory curves are eradicated and combine with dorsal recumbency extension of the head and pelvis with or without that of the legs also. Gradually the spasm is relieved, and then moderate hyperextension may be gradually employed with benefit. Should the case be one of cervical curves the head may be conveniently fixed in a box splint, traction applied to the head by means of an occipital band, the jacket and traction of the body serving as the counter-extension. It is not desirable to employ a chin strap, which is uncomfortable, and in children may cause deformity of the jaw. With much psoas spasm the contraindication known as the "wheelbarrow splint" is often effective. With moderate deformity without much muscular spasm the "swinging back-door" splint may be used to advantage. I have endeavored to suggest that while the standard spinal board described is of general value, the patient is most greatly helped if special appliances are utilized according to the ingenuity of the surgeon to meet existing needs, modified and altered as and when they arise. Other methods will naturally suggest themselves, designed for any complication, and thus every conceivable condition is countered by appropriate mechanical means.

There remains the consideration of extreme deformity resulting from tuberculous disease of the spine. It is often said that extreme deformity cannot be safely corrected, in children, at any rate, that is not always true. In a very large number of cases even extreme deformity may be often safely reduced, with great benefit to the patient. The most marked deformity occurs in the mid and lower dorsal regions. Deformity in spinal curves may always be prevented in both children and adults. Its correction when extreme is not easy, but it is often possible in children, and less frequently in adults. When associated with lateral curvature the most effective apparatus in my hands has been the "wheelbarrow" splint, followed by a carefully moulded

plaster jacket. Where there is an extreme kyphotic curve, hyperextension is not only impossible but cannot be tolerated. In such cases the only method which I have found to offer any prospect of success is by use of the apparatus known as the "Marconi" (Fig 2). The spine is further flexed until the compensatory curves are straightened out.

Fig 2 - Marconi apparatus for reducing severe spinal deformity

It will then be found that if the deformity is extreme the chest rests on the sternum, and that owing to the pre-existing lordosis and consequent shortening of the psoas muscles the thighs do not follow the line of the straightened lower portion of the spine, but are further flexed. Gentle traction on the legs gradually lengthens the psoas muscles and brings the thighs into alignment with the lower vertebrae. Traction on the pelvis and head in the direction the vertebrae now occupy corrects the compensatory curves and keeps them straight. Pressure immediately above, below, and at the angle of the deformity

reduces the angle formed by the disease, and gradually the deformity is reduced and the spine straightened.

The results of treatment are illustrated by an example (Figs 3 and 4). Lateral skilograms of the patient show that the angle of deformity has been definitely but safely widened. It need hardly be said that correction of such extreme deformity is not to be lightly undertaken and requires both patience and care. Where the slightest suggestion of commencing pressure on the cord occurs it must be abandoned. I would not recommend attempted correction of such extreme cases in other than special hospitals

for surgical tuberculosis, but in such institutions, with trained and intelligent nurses, attempts at reduction of such deformity may be undertaken with confidence and assurance.

When some dorsal deformity remains in a spine no longer active the apparatus known as the "push and pull" splint is often very effective. The pelvis is immobilized by a pelvic band. The patient is ventrally recumbent. A wedge pillow under the chest keeps the spine hyperextended. From the pelvic band ventral straps pass around each shoulder and are fixed behind the patient. They check forward movement of the trunk, but permit further dorsal flexion, which is encouraged. A padded dorsal board, as in the accompanying illustration (Fig 5), produces continuous gentle pressure on the deformity, and very gradually that deformity is diminished and at length corrected, with gratifying results. I conceive it to be of the utmost importance to correct or reduce deformity if possible, not only for aesthetic reasons but because by so doing the thoracic cavity is maintained as physiologically efficient as

Fig 3 and 4—Tuberculous disease of the spine treated on the Marconi apparatus

possible. There is less visceral displacement and the tendency to pulmonary complications which is the direct cause of early death in so many cases with badly deformed spines is very greatly reduced.

I agree with Rollier that in the final stages of the disease ventral recumbency with freedom to hyperextend the back is of value in improving the dorsal musculature, and is of value also in decreasing and preventing further deformity.

These are but examples of some means of preventing, or reducing deformity. They illustrate the desirability of utilizing standard methods of mechanical treatment

when such are possible, but also the necessity of being prepared to devise appropriate mechanical methods of treatment for particular cases when and where required. Again, we must always bear in mind that mechanical methods of correction of deformity are only justifiable when they are capable of safe employment, owing to the fact that the patient is tuberculous, unless attempts at correction of deformity involve a very real danger. Forceful correction of deformity in spinal curvatures is now a procedure of the past, and the techniques which followed attempts at correction by such means are a warning of their risk. I cannot resist quoting the following epigram, which is perhaps apt in this connection.

'Socrates, promising to set Diodorus' crooked back straight, piled three solid stones each four feet square, on the hunchback's spine. He was crushed and died but he has become straighter than a ruler.—Catheter from *The Greek Anthology* translated by W. R. Paton, vol. 1, 1918 p. 129.

FIG 5.—The push and pull splint

Nevertheless, by the exercise of judgement and common sense, most severe angular curvatures may be safely and widely reduced in children, at any rate, if suitable means be devised to this end at appropriate periods in the progress of the disease.

Time does not permit me to discuss at any length the use of plaster of Paris in the mechanical treatment of spinal curvatures. It is often of great value, and indeed, as Calot has remarked, it may be used quite efficiently as the sole mechanical method of treatment during the progress of the disease. My views as to its value are fully stated elsewhere. With modern developments of heliotherapeutic treatment the indications for its use are somewhat diminished. Nevertheless it is frequently of great value, particularly after correction of deformity and while consolidation of the lesion is taking place. It is also often indicated when it is desirable to intermit ambulatory with recumbent treatment. Sometimes a deeply situated abscess will remain stationary, being neither absorbed nor obliterated the patient may become toxicæmic. In such cases it is often wise to apply a carefully moulded plaster jacket with a large ventral window and to permit ambulatory treatment, sometimes with the direct object of encouraging the development of the abscess to enable aspiration to be undertaken. Again, in certain cases of chronic sinusses from the spine, ambulatory treatment in plaster often assists drainage, with advantage to the patient.

Lastly, I would allude somewhat briefly to the question of after-care. It has been asserted that in even the most mild infection in spinal curvatures three years must elapse before the inflamed infected bone is replaced by sound tissue. I have had no opportunity of verifying this statement, but imagine it has considerable truth. Absence of pain and onset of flexibility in the spine are valuable clinical signs suggesting arrest of the disease. Reclassification of the lesion with clear-cut outline of the part attacked is an important confirmatory x-ray finding. Added to these are you have the best guides in arriving at a decision of quiescence of the lesion. General constitutional signs will have generally completely subsided soon after adequate treatment is instituted and long before ambulatory treatment is even contemplated. But even when one is assured that ambulatory treatment may be safely started and the disease has been arrested, it is a wise precaution to insist on the application of a suitable mechanical protection for the spine in the form of a removable celluloid splint generally, I prefer a properly fitting jacket. Speaking to any other form of apparatus followed perhaps by a Taylor's brace or modification thereof. Such appliances may be worn without discomfort, and no valuable means of preventing late onset of deformity. In healthy subjects

with good musculature late onset of deformity is rare, if efficient and sufficiently prolonged treatment has been given. In cachectic subjects with poor musculature it may easily occur, even in the absence of active disease, but where adequate splinting has been neglected. In the former, while after-supervision is wise and desirable, it will be found that relapse and the development of deformity rarely follow unless ill health supervenes, or gross neglect and carelessness is shown. In the latter case the lack of proper subsequent supervision and the early abandonment of splinting means almost certain disaster.

The essentials in making celluloid jackets are (1) Careful moulding round the pelvis, from which support is derived, such moulding is obtained, not only by moulding the plaster cast when it is being applied to the downwards when the cast is being taken. The plaster is moulded well round the pelvis which act as counterpoints for pressure from the pelvis. The jacket, when made, will not ride up on the patient if it is moulded below the costal margin. In this way forward flexion of the spine is effectively prevented.

Orthopaedic Hospital.

OPERATIONS FOR SPINAL FIXATION
I do not quite share Sir Henry Graham's opinion regarding the part played by spinal fixation in the straightening of deformity. In 1919 I published a paper recording the results of fifty cases operated on, mostly by the Albee method, by my colleagues and myself. I then believed in the value of the operation at any age between infancy and senility. In 1923 I summarized the end-results of the original fifty cases with the results of another fifty I had either changed my opinion as to the need for the operation in children. Further experience has however, convinced me that in certain cases and at certain stages spinal fixation is indicated in children.

I felt then, and feel now, that operation is most valuable for adults, but definitely, in the words of Sir William Wheeler, as "part of the conservative treatment of Pott's disease." It shortens the need for recumbency, and there is no short cut to cure. I never cease writing and saying this, and learning it again and again myself by bitter experience. There is no short cut. In adult with the very greatest cure after he goes home. Calot emphasizes this, he says that the patients must be fit for several hours a day, go to bed early, avoid fatiguing work and sudden movements, and wear a splint (external or internal) for life.

To return to children the stage for operation is, I think, when the disease is quiescent, after several years' recumbency, and the cases are those where curvatures lead to such instability of the column as will through strain cause progressive deformity difficult to check by splintage,

and will also for the same reason be likely to lead to recurrence of disease

In lumbar and dorso lumbar cases an Albee graft is generally satisfactory, but in mid and upper dorsal cases a Hibbs's operation. I think a Hibbs's operation recommended by an osteoplastic graft (Delageniere) is best. Dr Philip Lewin of Chicago advocated this in the *Journal of Bone and Joint Surgery* in January, 1924, and Professor Osgood tells me he has been doing this operation for some time

The operation performed at this late stage, with the internal fixation it should produce, is really part of the after-care rather than the treatment, it is particularly indicated in cases in which recurrence of disease or increase of deformity is to be feared. I would strongly emphasize the advantage of using the "turning-case" technique, both for conservative treatment and during operation, as described in my article in the *British Journal of Surgery*, vol 1, No 39, 1923

THE DEFORMITY

The kyphos is determined in extent and in angle by the number of vertebrae attacked, the amount of bone destruction, and the site of the lesion. In considering the mechanics we may, for the moment, assume that there has been extensive bone destruction, but that everything has been done to limit the disease and heal it by general treatment and accurate splintage. The final essential of orthopaedic correction is stability, if telescoping and imbrication do not bring the bodies above and below the lesion into contact, angular curvature sufficient to do so is an advantage. Then with good compensatory curves, good musculature, and either a graft or, for a time at least, a good spinal support, the spine may be able to stand stress and strain without harm

That an angular deformity is right when there has been much loss of bone must not be forgotten, and the angle must be protected during the efforts to produce compensatory curves. Sir Henry Gairdner speaks of correcting the angular deformity, but we do not want to open up the angle, but rather to produce compensatory curves

SEPSIS

Sepsis is almost always a result of failure in early diagnosis or inefficient treatment. Elsewhere I have quoted Dr Rollier as saying "To open and drain a cold abscess is to commit a surgical crime." Rollier labelled such a surgeon "catastrophic," and said it was "almost a condemnation to death, not at once, but in two or three years," and added, "We cannot sting too much against it"

I have particulars of a series of 30 cases of tuberculosis of the spine admitted five years or more ago to the Wingfield Hospital, Headington. Of these patients 9 had been admitted to hospital with discharging sinuses, and 21 were admitted without open discharge. All the 21 patients, so far as I can ascertain, are alive at the present day, but 2 have definitely relapsed as a result of very bad home conditions and semi starvation, 3 others have required temporary readmission, but are doing well. So far as I can ascertain the other 16 are in good health and activity. Of the 9 septic patients 1 is well and at work, the other 8 are dead. May I repeat Dr Rollier's remark? "It is almost a condemnation to death, not at once, but in two or three years." Sepsis in spinal disease in adults is almost a sentence of death. How can we prevent it and how treat it?

Prevention of Sepsis

This includes (1) Early treatment (2) Efficient treatment, general and local, with careful aspiration, not too meddling and not too late (3) Long continued treatment (4) After-care, we must prevent relapse

Treatment of Sepsis

In the case of patients with sinuses there must be (1) efficient general treatment, (2) efficient immobilization and protection of the site of disease so long as there is active crises or instability of the vertebral column. When

this stage is long past, the patient may be allowed off his frame, on a light support, and, if not feverish, be allowed to get up for some hours each day

In a proportion of cases the sinuses will heal and the disease become quiescent. In others, probably the majority, the patients remain ill, and show signs of septic absorption, the discharge shows no sign of drying up—sometimes it comes freely, at other times there is swelling of the parts and retention of the pus. The patient is on the road to indurated disease, and unless we can alter this state of affairs altogether he will go straight on till he gets there, and it is a miserable destination. I have watched their last months

We must continue the general and local treatment of the disease as already outlined, applying every means of general treatment, including heliotherapy, open air, and a correct diet, but not overfeeding. In thoracic cases costo-transversectomy is sometimes advisable, and in lumbar disease an operation, such as that described by Treves in 1884. We must spare no pains in the effort to drain the fons et origo of the abscesses, freely, and by a route as short and direct as possible, and then we must keep up free direct drainage, often a recurring hateful task

Hospital Provision for Adults

Adults are often attacked by spinal tuberculosis, and of a grave type. They need prompt admission to a special hospital, even more urgently than young patients. Yet there is no provision for them at Alton, Heston, Lersow, Crishalton, and Pinfold. I do appeal that they shall not be overlooked in the new hospitals that are being developed. Joint and bone tuberculosis, with the accidents of industry and transport, provide the majority of adult patients needing orthopaedic in-patient treatment

Light—One last word as to heliotherapy. In our special hospitals we use open air, sunlight, the right diet, purposeful and accurate splintage, and an environment full of interest and happiness. It is dangerous to stress the light overmuch lest it lead to neglect of the other and more important factors

GENERAL DISCUSSION

Mr W. T. Gordon Pugh (Crishalton) said that he had always regarded bone-grafting the spine as unsuitable for children. In spinal crises the affected centra were decalcified to a marked degree, and the one essential in treatment was to keep the weight of the upper part of the body off the weakened centra. The operation endeavoured, by bringing the spinous processes together, to throw the whole of the weight on the articular processes. An examination of a child's skeleton suggested that this was mechanically unsound. The articular processes were only a short distance in front of the graft, whereas the weight of the body fell well in front of it, the latter had thus great leverage action, and, a child's articular processes being largely cartilaginous and not fitted to bear undue pressure, compression of the centra was not prevented. The weakness of the processes was accentuated by the fact that the plane of their articular surfaces was not horizontal but almost vertical. These facts and the fact that the graft was sometimes absorbed in children, had a bearing on the result. If, as not infrequently happened, too much reliance was placed on the operation and the recumbent position was given up too soon the weight produced collapse of the weakened bodies, the diseased tissues liquefied, and gravity quietly conducted the abscess into the groin, where it pointed. A number of cases had been received at Crishalton with septic sinuses that had originated in this way. When a sinus formed in these cases it was exceedingly difficult to get it to heal for the graft impeded the telescoping which usually played an important part in the healing of lumbar crises. The risks of the operation itself were almost negligible, but investigation of the end-results would prove unfavourable. In the case of children he advocated prolonged recumbency. There had never yet been devised a jacket or splint or, in his opinion, operation which was capable of relieving the diseased vertebral bodies of an erect child from super-

incumbent weight. By recumbency deformity could be prevented if the patient came under treatment early enough, and, if already present, could be lessened by a flattening of the spinous processes and by a modification of the natural curvature of the healthy part of the spine to compensate for the abnormal curve in the diseased section. Sir H. Gauvain had stated that he applied hyperextension at the seat of disease. With this the speaker did not agree, so far as the dorsal region of the spine was concerned at any rate, where the close approximation of laminae and spinous processes prevented hyperextension taking place without separation of the surfaces of the diseased vertebral bodies. Such separation was not conducive to bone formation in the affected region, it prolonged the treatment and was often followed by recurrence of deformity. The bend in the spinal frame should be placed above the seat of disease if this were in the lower part of the spine, and below it if the upper part were affected. Growth was naturally stunted in the diseased centre, but would go on normally in the healthy ones, with the result that a prominence which appeared to occupy a considerable fraction of a young child's spine would become much less obvious after some years' growth, provided that a compensating modification of the curvature of the rest of the spine was secured. Two-thirds of the cases began under the age of 6, and the curves of the growing spine were readily modified. When the period of recumbency was over a jacket should be worn, extending anteriorly well up in front of the shoulders but behind only to the point at which the bend in the frame had been made, so that the continued production of the compensating curve might be encouraged. It was now fairly generally recognized that a jacket could not take off weight, and that its function was to prevent flexion compression of the diseased area and to maintain or increase compensatory curvature.

Mr D. McCRAE AITKEN (London) said that although he agreed with the opener that the nature of the splint did not matter, because a skilful surgeon would make his splints effective, yet the teaching was very dangerous. More particularly he attacked the apparatus called the "push and pull" splint, which the opener had said was only to be used when the disease was completely quiescent. Sir Henry Gauvain had lived constantly with tuberculous disease for many years, and perhaps he could be sure that the disease was cured and that there was only residual deformity to be corrected. Sir Henry used apparatus which allowed much more mobility than the splint would do to permit, and certainly he would not recommend it. He regretted that the opener had attacked fixation operations such as the Albee bone graft operation. Mr McCRAE AITKEN had for many years performed the bone graft operation, at one time almost as a routine. He agreed with Mr Pugh that it was not an operation for young children, except perhaps in very special cases. Nearly twenty-five years ago, when he was Sir Robert Jones's house surgeon, in discussing results with other house-surgeons, it was said that the spinal cases did not do well unless kept fixed for about five to seven years, and that five years' recumbency in a Thomas frame was not too long to get a really good result. Having performed Albee's operation for the last dozen years or so, he was prepared to say that it did not greatly shorten the period during which some sort of spinal support should be worn. He believed that he employed the bone graft in the spine exactly as he used a graft or sliding graft in an ununited transverse fracture in the humerus—namely, to check small local lateral movements which were preventing ossification and were not properly controlled by external splints. It was therefore of value in hastening repair, but was not a substitute for a back brace or a back support. He had performed the operation in a child as young as 8 or 9 years of age, the graft or the bone which grew in its place grew with the child, and would inevitably bend if it was expected to take the place of the destroyed bodies. It was necessary to wait for effective bone formation in the region of the bodies before dispensing with spinal supports. In adolescents and adults rapid healing was essential to a good end-result, therefore a graft was more often called for as an aid to fixation. Of the regions of the body in which it

was most strikingly effective the cervical region came first and the lumbar region second. The imbricated arrangement of the vertebrae in the dorsal region made injurious lateral movements less likely. Finally, the deformity should be corrected as fully as possible before operation. This meant correction in recumbency for periods up to perhaps two years or more before operation was thought of. If possible he liked to correct the deformity, as Sir Henry Gauvain had described, at the seat of disease, but that was only possible in early cases in children, such as he was accustomed to handling at Alton. In later cases, where there was already consolidation at the seat of disease, the method of compensatory correction described by Mr Pugh must be used. Early operation in a case of active disease with gross deformity, in a desperate hope that the bone graft would steady the part and hasten recovery, had been a total failure. If the deformity could not be corrected the body weight would put a cross-strain on the part and relapse was liable to occur. If the case was one in which the deformity could be corrected quickly, then an early operation was a help in getting more rapid consolidation at the seat of disease.

Mr F. C. PAIN (Newcastle-on-Tyne) thought that the results shown by Sir Henry Gauvain emphasized the need for special hospitals, specially trained staffs, and after-care associations. He spoke as a general surgeon who had been compelled to treat many such cases under considerable difficulties. He emphasized the need for prolonged treatment, not one or two years, but for four or six. In determining when a case might be considered cured clinical signs were useful, but x-rays were more valuable, showing the fusion of the vertebrae with a clean-cut appearance. When a person's abscess increased in spite of rest or aspiration, or for other reasons, a radical cure could be undertaken, although it must be recognized that the abscess was a complication and not the disease. The main drawback of the operation was the infection of the wound with tubercle bacilli, aseptic healing occurred, but later broke down. He described his operative procedure, which included careful exposure and definition of the sac, protection of the wound, aspiration to evacuate the pus, opening the sac and dry scrubbing to remove pyogenic membrane, treating the inside of the cavity with iodine, and closure of the cavity and wound. With perfect technique no single organism from without or within must be allowed to come into contact with the wound. Good results would then be almost certainly obtained.

Mr ALAN SMITH (Cudiff) held that the question of treatment depended, from the national standpoint, on an adequacy of open air beds. No ambulant treatment would do away with the necessity for prolonged recumbency. The Welsh National Memorial Association, on account of its insufficient surgical beds, had to make arrangements for plaster fixation and immobilization at home pending admission. This was a poor compromise any ambulant fixative treatment depended on the efficiency of after-care schemes and the fineness of the mesh of their network. When or how were they going to obtain osseous or fibro-osseous fixation of the central remnant? Did anyone know the number of cases who recovered without or with inadequate treatment? Those who were seen in middle life were dwarfed and had a large deformity, but they were apparently fairly fit. Did one get a better fixation of the central fragments by this crushing effect of body weight? He was somewhat conservative in bone-grafting, he did it in adults where the kyphos was not greater than 45 degrees, and only after preliminary recumbency until the generalized condition became subacute. The operation was merely an addition to the other methods of fixation. He mentioned the question of paraplegia in adults, in children recumbency in hyperextension was generally sufficient to produce a reduction of the granulomatous pressure on the meninges. He had performed a decompressive laminectomy in adults, and had removed a thickened doughy granuloma from the dura, with a complete cessation of symptoms and subsequent recovery. In such cases Calve's aspiration would be useless as the granulation tissue did not break down to pus.

Mr R C ELMSLIE (London) pointed out that the diminution in the number of cases of severe deformity was very evident in two surveys of the children in the London County Council schools for crippled children made in 1907 and in 1922. This improvement was largely due to the increase in special hospital accommodation, but he thought that Sir Henry Grayan might have given some credit to the teaching of early diagnosis in the medical schools. Mr Elmslie doubted whether the correction of deformity at the site of the disease was advisable. He had always considered that it was necessary to allow a moderate degree of collapse, in fact, he understood that this was one of the arguments made against the bone graft operation, of which he was still an advocate. He performed the operation almost as a routine for adults, and although he had given it up for children for ten years he was not sure that he was right. The trouble was that the operation had been so much misused. It was not a cure for the disease, but only a form of internal splint, it should be performed only after preliminary treatment, and followed up by rest and hygienic treatment.

Mr H A T FAIRBANK (London) referred to differential diagnosis in children. He thought it was not superfluous to insist on the absolute necessity of having first-class stereoscopic radiograms before giving a decision in a difficult case. In his experience developmental error and new growth had given the greatest difficulty. He showed radiograms of two cases of congenital abnormality in which mistakes in diagnosis had been made. The first had been regarded as tuberculous and treated as such for five years. There were two abnormal sites, both in the lumbar spine. The lower was, at first, regarded as congenital defect, the upper as caries, but recent x-ray examination showed that both were congenital abnormalities, with fusion of laminae and spinous processes, and, at one spot, also of two bodies. In the other, in which he himself had made a mistake, the lumbar spine was again affected. As an example of sarcoma in a child he showed radiograms of a girl, aged 11, with clear areas in the tenth dorsal body and a long opacity in front of the bodies some vertebrae higher up. The two lesions should have suggested the correct diagnosis. The child had a progressive paraplegia with anaesthesia. He performed laminectomy, and found a sarcomatous mass surrounding the thorax. As a contrast to the last he showed a radiogram illustrating two distinct lesions of the spine. He had grafted the lower, and only discovered the upper at a later date, though it was probably present at the time of operation. He had met with other similar cases of double lesion. After grafting a small series of cases in children he had given it up, and now would not graft under the age of 14. He thought it possible that in the future they might come to fixing a smaller extent of the spine as a routine than was done at present. He had had grafts fracture some months after insertion. He thought it possible the shorter graft would be as efficient as the longer. As to abscess, all agreed that in draining abscess without skin involvement aspiration was the treatment. When the skin was involved and about to give way, opinions as to treatment differed. He preferred excision of involved skin and closure of wound in the hope of getting healing, and even repetition of this procedure. When there was a discharging abscess with obvious mixed infection, free drainage was indicated. Lastly, he showed radiograms of two cases of atlanto-axoid disease, with marked displacement of the atlas, but without paralytic complications.

Mr T P McMURRAY (Liverpool) was glad to notice that all agreed as to the essential part which prolonged fixation held in regard to the treatment of tuberculous disease of the spine. Other factors were present and helped to a greater or a lesser degree, but in his opinion the essential part of any efficient treatment was a complete fixation which allowed the consolidation of the fibrous tissue and the destruction of the living tubercle bacilli. In his opinion this fixation could be employed to its best advantage by means of a frame which fixed the child's body, head, and legs, and so prevented the irritation of the diseased area.

As regards operative treatment, this should only be employed after the consideration of all the conditions, and should not be employed in any circumstances in children. In its essentials operative fixation of the spine was only an attempt to shorten the period of recumbency with fixation, and was not, and never could be, so satisfactory a fixation as the former. It was impossible to say what length of time was necessary for the cure of tuberculosis, but there were certain clinical signs which helped in estimating the stage of the disease. If no abscess formation could be shown by the x rays, if there was no exaggeration of reflexes present, if pain had disappeared completely for at least a year, then more freedom was justified, and the period of recumbency could, with some degree of safety, be brought to a close. The disadvantage of the operative fixation of the spine was that the surgeon was tempted so to reduce the period of fixation that cure of the disease was much less likely. In two cases of tuberculous spine in children, in whom a successful bone-grafting operation had been performed and the patients allowed up after a period of nine months, pyous abscesses developed in both cases, although the bony fixation was complete. Thus, in his opinion, was the great error of the matter. They knew that the cure of tuberculous infection could be obtained by prolonged fixation, then why not always use this method in children?

In adults another factor entered into the problem. Usually the patient could ill afford two or three years of recumbency, and also the adult patient did not react to prolonged fixation as well as the child. Here the operation of bony fixation was justified, even though it involved a percentage of risk which was not present with the other form of treatment, and the operation was especially useful in the lumbar region. No form of brace or support could possibly prevent the movement of the spine in this region. As each movement of the hip was accompanied by a rotation of the lumbar spine due to the action of the psoas muscle, bony fixation of the spine in this area would undoubtedly help, and would enable the patient at an earlier period to return to his or her duties. One other very important point had been brought up in the discussion, and that was the treatment of the chronically discharging pyous abscess. He had found that several of these cases, which had resisted all forms of local and general treatment for years cleared up very rapidly when the period of recumbency had been brought to an end, and the patient had been allowed to walk about with the proper form of posterior support. Whether the cure was better drainage or increased vascularization of the abscess wall or a combination of both—this seemed the most probable—this method had been successful in several chronic cases.

Dr ROBERT B OSGOOD (Boston, U.S.A.) said that in America they were equally convinced that the treatment of the tuberculous bone and joint lesions was primarily the treatment of the general disease, aided by those surgical procedures and mechanical appliances which the morbid process demanded. They were therefore stressing as a *sine qua non* recumbency in the fresh sun-washed and wind-washed air, heliotherapy, and an antituberculosis diet. In the acute stages in children they immobilized them as completely as possible, either on frames, or more often in the specially made plaster shells of Schwartz* striving if deformity existed, to reduce the obvious kyphos by producing compensatory curves above and below according to the safe rules of leverage laid down by Schwartz. He reminded them that absolute and complete immobilization of the spine was impossible, unless they restricted normal respiratory movements to a hardly to be desired extent, relative immobilization was all they could attain. As the activity of the disease became less they were inclined to insist on less and less complete immobilization as long as the reflex irritability remained absent. They agreed as to the wisdom of recumbency for one two and generally for three years in young children, they believed in the aspiration and not the open incision of abscesses. The commission appointed by the American Orthopedic Association in 1920 to study the

*See The mechanics of a new plaster shell in the treatment of Pott's disease in children with lateral x-ray control by R. Plato Schwartz, A.B., *Journal of Bone and Joint Surgery* October, 1922, p. 787.

end results of ankylosing operations on the spine in young children reported, he thought, (1) that the operations had, in well trained hands, an almost negligible mortality, (2) that ankylosing the spine did not of itself cure the disease, surely influenced favourably a paraplegia, or prevented an early ease from going on to deformity. They had, therefore, at the Boston Children's Hospital rarely performed the operation until they believed the disease to be quiescent, and even then in only a few instances. At present he advised some form of ankylosing operation after the disease appeared to be entirely quiescent, if not cured, and as complete as possible redressment obtained. Waldenström's report of one hundred cases of this sort without a death attributable to the operation, covering a period of ten years, 1909-19, had fortified their opinion, and his careful end result studies were most encouraging. The type of operation which he had performed was the Albee, and he was apparently satisfied with it. They had been employing the fusion operation of Hibbs, not always antiseptising the intervertebral articulations, but splitting the spinous processes vertically, turning the leaves up and down, and making the chips turned up and down from the laminae interdigitate—as Mackenzie Forbes had described it, making a veritable forest of bone. Over the flat bleeding chip strown surface they applied a flat, flexible, ribbon like osteo-periosteal graft removed from the tibia, and they expected firm ankylosis. They thought it should provide a local internal splint, more efficient than any external splint, that it might be obtained without appreciable or unavailing risk, and that it made the wearing of a lighter or no apparatus safe, and the development of gravity deformity less likely. In Boston, he thought, they were inclined to advise an ankylosing operation in adults earlier and more constantly than in children, for the reasons that had been so well stated by the other speakers. The Albee type was more easy and quicker than the Hibbs, and the fate of the graft with wide spinous process contacts was more certain. Dr Calvé's trocar for aspiration of spinal abscesses through the intervertebral foramen was most ingenious, and in his hands and in those of others was seemingly devoid of the hazard it suggested. In two recent cases they had found on laminectomy such solid tuberculous granulation tissue that it could not have been drained. Mr Lambank had too modestly suggested that the differential diagnosis of tuberculous eries of the spine was not always easy. They had mistaken syphilis, metastatic carcinoma, sarcoma, and multiple myelomata for tuberculosis, and performed useless operations for ankylosing the spine. Mr Fairbank had also pointed out the comparative frequency of multiple foci of tuberculous disease of the vertebra. These also they had so often overlooked that they now insisted upon complete spinal radiograms before treating the obvious lesion.

Mr S W Daw (Leeds) thought that no diagnosis should be made without x-ray evidence, and believed that at the stage of the onset of clinical symptoms changes demonstrable by the x-rays were well advanced. A narrowing of one or more intervertebral discs usually occurred, and there was a type of case with narrowing of a vertebra but without narrowing of the adjacent discs. He would like to be satisfied that this was really tuberculous eries. As regards abscess, the results of modern treatment made one more optimistic than formerly. Abscesses generally disappeared with rest, with or without aspiration, open operation was very much required. With reference to bone-grafting there were theoretical grounds on which this operation was difficult to defend, since it would appear to interfere with collapse and consolidation leading to cure, and it also seemed likely to prevent the necessary compensatory atrophy of the posterior elements of the spinal column at the site of the lesion. As a practical measure it was extremely successful, however, and he urged that if it was particularly suitable for hard workers, as had been stated, then it must be a good operation for other classes of adults. Bone-grafting by two lateral grafts had become almost a routine treatment for spinal eries in Leeds as regards adult patients. Children were not bone-grafted. In cases of paraplegia, suitable splinting

would usually bring recovery. Aspiration of an abscess close to the spine was sometimes necessary and successful. If long continued conservative treatment failed to relieve the paralysis, laminectomy without opening the dura mater should be performed, this generally relieved pressure sufficiently. Opening the dura mater would seem to involve danger of infection of the cord with tuberculosis, and was to be avoided if possible.

Dr HARRY MARTIN (Liverpool) wished to point out that in his opinion the methods adopted for the correction of kyphosis in tuberculous disease of the spine should depend on the stage of the disease. He had found that in early cases with acute kyphosis it was possible to attempt correction at the level of the kyphos, to "open out" the affected vertebrae, and to secure correction by calcification of the fibrous tissue replacing the destroyed vertebral bodies. He felt that in later cases where the anterior ligaments of the spine had contracted beyond the point whence they could be stretched, that the methods of Schwartz, which produced a lordosis above and below the kyphos, were the most satisfactory in the prevention of increase of kyphosis. With regard to Calvé's aspiration of abscesses within the spinal canal, he wished to differ from some of the previous speakers that the operation was attended with risk of damage to the spinal cord, performing the aspiration on the cadaver would prove this to the uninitiated. He felt that the surgeon should be prepared to go further in his search for causes of pressure in the event of the aspiration through the intervertebral canal being unsuccessful.

Mr W I DE CONEY WURRIN (Dublin) said that he had performed forty consecutive bone grafts without a death or complication for spinal tuberculosis. He never operated upon children. The operation was a simple one, and consisted in making a fresh bony bed under the erector spinae muscle on one side and placing a long substantial graft from the tibia in the prepared bed. The patients were kept on a double Thomas frame for three months and in bed with a posterior spinal support for a year. The cases were watched closely for a long period. The bony bed was freshened by a special raspator bent to a suitable angle. In dealing with persons abscess in adults which resisted fixation and aspiration, he packed the cavity with gauze smeared with bipp, and stitched the wound up completely with the gauze *in situ*. In two days the gauze was removed through a small additional opening, which was then immediately closed. Many cases so treated gave no further trouble.

Mr HENRY GAYLOR, replying, said he was sure he voiced the feelings of the Section in thanking their distinguished American colleague, Professor Osgood, for his illuminating contribution, the outcome of an immense experience. They would also join him in welcoming back Mr McCrae Arthur after his illness, and in rejoicing at his restoration to health as shown by his vigorous criticism. Experience with chronic tuberculous cripples at Alton had taught him that the very strict immobilization over a prolonged period formerly practised was unnecessary and often undesirable when all signs of activity had completely subsided. The discussion, which had largely centred round operative measures in the treatment of spinal eries, had been undoubtedly helpful.

OBSERVATIONS ON THE OSGOOD SCHLATTER DISEASE

By

ROBERT OLLFRENSEHAW, F.R.C.S.F.,
Orthopaedic Surgeon to the Royal Manchester Children's Hospital

SINCE 1903, when Dr Osgood described ten cases of lesions of the tibial tubercle in adolescents, a good deal of interest has been taken in this condition. Five years later Schlatter published an account of further instances, and many later writers have discussed causes and pathology, and in some cases have cast a certain obscurity over the condition—an obscurity which, to my mind, is quite unwarranted. In the

most recent French textbook on the surgery of childhood the author makes the pathology both complex and uncertain. I would like to say, therefore, at the outset, that as a result of personal investigation and treatment of thirty-two cases, I have come to the conclusion that the condition, which certainly does show some clinical variations, has a purely traumatic origin, a definite pathology, and a clear line of treatment. Strains thrown on the terminal portion of the quadriceps mechanism are common and, at different ages, produce varying lesions—in elderly people fracture of the

FIG 1 shows the left knee of a girl aged 14 who fell from a swing and who reported that both knees struck the ground. There was well marked tenderness and some swelling of the tibial tubercle and the figure shows separation of a fragment.

FIG 2 shows the right knee of the same patient and whilst the tubercle of the tibia was normal radiographically and clinically the lower edge of the patella was torn off and this area was very tender to pressure.

FIG 3 shows the left knee of a boy aged 15 who had a fall in the gymnasium and hurt both knees. The figure shows a separation of the tibial tubercle.

FIG 4 shows a fracture of the patella in the right knee.

FIG 5 shows the right knee of a girl aged 13 who fell from a haystack. She did not actually fall on the knees but jumped and fell awkwardly. The right knee shows a fracture of the patella.

FIG 6 shows the separation of the tubercle of the tibia in the left knee.

patella or rupture of the tendon above the patella, a condition of which I have had two recent personal experiences. In the middle aged fracture of the patella is the common result. In adolescence avulsion or separation of a fragment of the tibial tubercle, or a fracture of the lower border of the patella, may occur. I regard, therefore, what is known as Osgood's, or Schlatter's, disease as the representative in childhood of the fracture of the patella in the adult. I am sure that the two lesions of childhood—(1) separation of the tibial tubercle, and (2) fracture of the lower edge of the patella—are due to the same cause, because I have had three patients in whom both knees were simultaneously and similarly injured, and on examination one knee showed a separation of the tibial tubercle, whilst the other showed a torn-off lower edge of the patella.

Treatment

I think this lesion is a fracture and should be treated as a fracture by complete immobilization for six weeks. I find that the best immobilization is achieved by a well fitting plaster cast, fitted close to the limb and moulded closely round the knee. It reaches from the groin to the ankle and,

whilst it is worn, walking is permitted. After removal of the cast massage is instituted and a knee cage, with a stop allowing only 45 degrees of flexion, is worn for a further six weeks. The cases which I have seen where symptoms have persisted for months or years, and which have been called "apophysitis," "periostitis" either traumatic or mildly infective, or the like, have in every instance been the cases which have not been treated by immobilization, but where continued strain has been allowed to take place.

Most of these cases which one sees later in the day settle down well and consolidate if completely immobilized in the same manner as is advised for the recent cases, but a few old standing cases where a tender non-union exists are improved by operative fixation of the fragment to the diaphysis. Many textbooks, in a scant reference to the subject, say that the "slightest cases" may be treated by strapping or a little rest. In a case reported in the same journal in which Dr Osgood's original paper appeared, I came across the following case report of a separated tibial tubercle in a girl: "Under treatment by strapping the leg became almost functionally perfect, and aside from slight pain on pressure, or when kneeling, she has recovered." I should like to hazard a guess that the result remained almost perfect, and that the tenderness on kneeling and pain on pressure remained for many months or even years.

In my series of cases more than half (nineteen) occurred in girls, though it is generally stated that the condition is more frequent in boys. Dr Osgood's original ten cases were all in boys, and in drawing attention to this fact he attributed it to the increased athletic activities of boys. I can only suppose that the young ladies of the North of England, where I work, must be more "tomboyish" and less prim and proper than their sisters of Boston, Mass.

DISCUSSION

Dr ROBERT B OSGOOD (Boston, U.S.A.) agreed with Mr Ollerenshaw as to the pathology of the lesion. He had found that treatment with adhesive plaster strapping was generally sufficient without use of a plaster splint. He called attention to the two methods of development of the tibial tubercle—the one as a tongue-like extension from the upper tibial epiphysis, and the other as a separate osseous centre which later joined with the upper tibial epiphysis. He emphasized the importance of having both these in the same plane in a case of suspected lesion of one side, since the variation in the development of the tubercle differed so much within normal limits. By experiments on the cadaver he had found that the chief pull on the tubercle was exerted in the last five or ten degrees of complete extension, the patella tendon proper being then most tense while the lateral expansions of the quadriceps were entirely capable, with the tubercle detached, of extending the knee to within five degrees of complete extension.

THE eleventh French Congress of Forensic Medicine will be held in Paris in May, 1926 under the presidency of Dr Antheaume, general secretary of the Society of Forensic Medicine in France. The subjects to be discussed include the dosage of alcohol in the blood and the diagnosis of intoxication introduced by Dr Viellend of Lille, the psychologist as an expert witness introduced by Dr Roques de Lursac of Paris, and traumatic arthritis, excluding tuberculosis, introduced by Dr Derieux of Paris. The general secretary of the congress is Dr Etienne Martin, Lyons.

EXTRADURAL SPINAL MENINGEAL HAEMOR- RHAGE WITHOUT GROSS INJURY TO SPINAL COLUMN

We venture to place on record the following instance of death occurring after an apparently trivial accident, as we think such cases must be extremely rare

Whilst cycling to her work about 2 p.m. on September 6th, 1924, a shop assistant came into collision with a motor car, and fell off her bicycle on to her left side, bruising her left arm. The accident was most trivial, as the car was only going about five miles an hour at the time of contact, and never touched the cyclist whose front wheel struck obliquely the running board of the car.

She went to work by bus immediately after the accident and on the following day, Sunday, felt quite well, except for a little stiffness in her arm and slight pain in her back. On September 8th she did not feel quite so well, and remained at home, on the next day, September 9th, as she felt much worse, she came to see us about 7.30 p.m. Her expression was anxious, the face flushed, and she complained of pain in her back, which was most apparent when she attempted to rise to her feet after sitting down. The temperature was 101°, the pulse 110, she was menstruating, the pupils were normal, and there was no trouble with bowels or bladder. The knee jerks were present but not brisk. She walked across the study perfectly well, and had come from her house, a distance of about a mile, apparently without much difficulty. We sent her home to bed at once, and the next morning examined her thoroughly; the temperature then was 100°, pulse 110, she was quite conscious, pupils normal, there was flaccid paralysis of the right leg and partial of the left leg, no vomiting, the bowels had not acted since September 9th. There were no bladder symptoms, no signs of bruising in the lumbar region or spinal damage of any sort, zones of ovarian hyperaesthesia were well marked. She had been previously attended by us for dysmenorrhoea and its attendant neurosis. We saw her again on September 11th, when her condition was much worse—temperature 100°, pulse 115, flaccid paralysis of both legs, loss of all reflexes and sensation, and paralysis beginning in arms. She was very anxious but conscious with jerking respirations. The bowels acted in the morning, there were no bladder symptoms. She was seen again at 3 p.m., when she had become much worse and the respiratory centre began to fail. She was still conscious and paralysis of arms and legs was complete. Spinal puncture was considered, but deemed inadvisable owing to her condition. At 5 p.m. she was in a moribund state, and died at 8.30 p.m.

The post mortem examination revealed extensive extradural meningeal haemorrhage, extending the whole length of the cord up as far as the level of the third cervical vertebra, tuberculous foci in both tubes, lungs, and an area about the size of half a crown on the meninges in the occipital region. There was no sign of tuberculous foci in meninges of cord, no fracture or dislocation of column, and the actual vessel from which haemorrhage originated was not discovered.

The haemorrhage in this case undoubtedly started in the lumbar region, and must, to begin with, have been extremely slight, possibly stopping altogether for some time, when it began to recur and continued until it reached the level of the third cervical vertebra, and paralysis of the phrenic ensued. We suppose that a wrench or twist of the spinal column at the time of the accident caused the rupture of a small vessel.

FULL-TERM MULTIPLE PREGNANCY IN A UTERUS BICORNIS BICOLLIS

The condition found in the case here recorded is sufficiently rare to merit publication.

A woman, aged 25, 6 para, who in August, 1917, and February and December 1918, had had miscarriages, and in 1920 and 1924 had full term deliveries of live children, was admitted to the Lady Reading Hospital, Simla, on September 17th, 1925, in the ninth month of pregnancy complaining of great abdominal discomfort and difficulty in breathing. The abdomen was greatly distended. Two foetuses could be palpated, and there was some excess of liquor amni. Early the next day the membranes ruptured. A few hours later a healthy female child was born. Immediately after the birth of the child there was very severe haemorrhage. On vaginal examination the placenta was found protruding through a cervix lying on the left of the vagina. It was removed. The uterus at once contracted down and the haemorrhage ceased. On further examination the second child was found to be lying transversely in a second uterus on the right of the abdomen. By vaginal examination a second cervix was found very high up on the right and separated from the first by a thick fleshy mass. This cervix felt very hard and resistant and was dilated about one third. There were no apparent con-

tractions in this uterus. After waiting about two hours, as no pains came on and the child was lying transversely, the membranes were ruptured and a foot brought down. After fifteen hours it was still no pains in the right uterus although there were severe after pains in the uterus on the left, the cervix, however, was found almost fully dilated and the buttocks in the vagina. As the child's condition was becoming serious it was decided to extract. This was done with considerable difficulty and the child was stillborn. There was no haemorrhage after the delivery, and the placenta was expelled after a few minutes. On abdominal examination the two uteri could be felt as two separate hard balls, quite distinct from one another. Convalescence was uneventful, except that after pains were severe for three days first in one uterus and then in the other.

Medical Superintendent, Lady Reading
Hospital, Simla.

RENAL DECAPSULATION IN ACUTE NEPHRITIS WITH ANURIA

I HAVE seen little or nothing in recent British literature dealing with renal decapsulation in acute nephritis, and it appears to me that all cases in which this operation is done should be recorded, whether the result be failure or success. I was much encouraged in giving my patient what seemed to be his only hope by an article by Sir Thomas Holder in the BRITISH MEDICAL JOURNAL of November 13th, 1920, entitled "Treatment of subacute nephritis by kidney decapsulation," in the course of which he said, "One other clinical type of nephritis requires brief mention, and that is acute nephritis puncture or incision of acutely inflamed kidneys is, in my opinion, quite justified whenever anuria and uraemia persist despite energetic general measures."

While I feel convinced that the operation saved the patient's life in the following case, I, of course, do not mean to suggest that every patient with nephritis should be operated on. I suggest, however, that a patient suffering from acute nephritis should not be allowed to die from anuria without renal decapsulation having been tried. The operation may prove to be without value, but it should not be condemned without a trial in a reasonable number of cases. Would it not be logical to go a step further and try the effect of renal decapsulation (or nephrotomy) on patients suffering from blackwater fever with anuria? With the usual treatment the mortality in these cases is so very high that the experiment would seem to be quite justifiable.

The operation is not difficult and does not demand much skilled assistance or special instruments. Chloroform, I imagine, would not be safe in these cases, and gas and oxygen would not be available in remote places in the tropics, but a spinal syringe and a few ampoules of storaine can easily be included in the medical officer's equipment.

R. F. K., aged 37, had blackwater fever some years before the war. While a prisoner of war in Germany he had a feverish attack and passed little or no urine for a day or two.

History of Present Illness

On September 27th, 1924, he felt feverish (temperature 102.8°). He complained of no particular symptoms, and examination was negative. The following day the temperature was normal. No urine was passed, there were no symptoms. On September 29th and 30th the temperature continued normal. About 3 drachms of urine was passed, it contained much albumin, some blood, some pus, and an enormous number of casts. The patient was given plenty of bland liquid, diuretic, laxative, etc.

On October 1st the temperature was 97.6°, pulse 52. Two drachms of urine was withdrawn by catheter. A skagram of the kidneys and ureters revealed nothing abnormal. The following day no urine was passed. The passage of a catheter showed the bladder to be empty. The patient exhibited well marked signs of uraemia and was clearly becoming rapidly worse.

Operation

Dr. A. Morrison and Dr. S. Forrest, who saw him in consultation, agreed with me that the condition was desperate, and that it was justifiable to try a renal decapsulation in what was all regarded as a forlorn hope.

Under spinal anaesthesia (storaine) the left kidney was decapsulated at 6 p.m. The capsule was adherent to the renal tissue and its separation caused free oozing. The wound was completely closed and healed by first intention. The patient improved rapidly and caused little further anxiety.

The excretion of urine after operation was as follows: October 3rd 4½ oz. October 4th 6 oz. October 5th 9½ oz. October 6th 21 oz. (traces of albumin, a few red cells, urea 95 grams per litre). October 7th 51 oz. October 8th 75 oz. The urine rapidly returned to normal and has remained so since. The patient is in excellent health.

Schutz, Alexandria, Egypt.

E. N. RUSSELL, M.D.

STRANGULATION BY UMBILICAL CORD

On August 1st I was called to Mrs C, a 2-par. The unruptured membranes were bulging at the vulva. The presentation could not be made out, the skull bones feeling loose and plate-like. During a pain the membranes ruptured, allowing the escape of dark brown fluid. The head was delivered, and the shoulders followed with some difficulty. The cord was tightly encircling the neck once, and was so tight that it was necessary to cut it. The child had been dead some days, being macerated. The head and neck were deeply congested, and there was a distinct groove round the neck. The appearance of the eyes, partly opened, was characteristic.

This case is of interest from a medico-legal point of view.

P HENDERSON, M.D., L.R.C.P. and S
Seghill Northumberland.

British Medical Association

CLINICAL AND SCIENTIFIC PROCEEDINGS

OXFORD DIVISION

THE fifth meeting of the year of the Oxford Division of the British Medical Association was held in the Radcliffe Infirmary on October 28th, when Dr A W NELL was in the chair.

Dr W COLLIER, sen, read notes of a case in which the diagnosis between gall stone colic and abdominal angina was difficult.

A woman aged 48 had had two previous attacks of gall stone colic twenty four and four years respectively before her last (fatal) illness, which commenced one week before death with repeated attacks of severe abdominal pain and vomiting of bile. The pain was not quite typical of gall stone colic and in view of the cardiac enlargement and the irregularity of the heart's action the possibility of angina was at first considered. Later the gall bladder was found enlarged and hard and it appeared to contain a stone. The patient died suddenly two days after admission to hospital. At the necropsy the pericardial sac was found full of fluid and clotted blood, the heart was hypertrophied, mainly on the left side and, on the posterior aspect of the apex there was a rupture three quarters of an inch long, surrounded by a rough haemorrhagic clot. The tip of the left ventricle was much thinned and infiltrated with clot extending up the wall as far as the posterior capillary muscle, and also up the anterior wall, was an area of ischaemic necrosis, apparently in the distribution of the descending septal branch of the right coronary artery, where this became too small for naked eye dissection. The main coronary arteries were patent and contained no clot or embolus. The valves were healthy and the pulmonary artery contained liquid blood. In the gall bladder a large stone was present.

There was nothing in the patient's history to suggest syphilis, but a fairly pronounced history of alcohol was obtained.

Dr J RICKARDS showed a woman, aged 69, with chronic intestinal obstruction. She was suffering from emaciation and abdominal pain, and the abdomen showed peristalsis and a ladder pattern.

Dr A G GIBSON showed a boy, aged 7, with sequels of an attack of encephalitis lethargica in the early part of the year. The boy was duller than normal and was subject to attacks of vomiting. The eyes were rather staring and there was overaction of the levator muscles of the eyelids, with feeble accommodation reflexes and slight nystagmus. In walking he tended to keep the left arm still, while swinging the right arm.

Professor R A PETERS gave a lantern demonstration on recent researches in rickets. He showed how the rival and apparently contradictory dietetic and hygienic theories of the causation of rickets had been harmonized by another factor—namely, the action of light on the body. Radiation could confer curative properties on foods which were otherwise useless.

The unfavourable verdict on oatmeal which had been pronounced by Professor Mellanby called forth vigorous protests from the Scottish members present, and it was suggested that any alleged rickets-producing factor in oatmeal might be more than compensated by judicious use of the national beverage and by the free radiation treatment of kilted lower limbs!

Reports of Societies.

INFLUENCE OF THE OVARY IN PARTURITION

At a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on November 10th with Dr GEORGE GRAHAM in the chair, a brief account was given by Mr F H A MARSHALL, Sc.D., F.R.S. (Reader in Agricultural Physiology, Cambridge) and Professor W L DIXON, M.D., F.R.S. (Reader in Pharmacology, Cambridge), on some recent work to determine the influence of the ovary in parturition.

Dr Marshall said that it was certain experiments in pseudo-pregnancy produced in rabbits which led up to the theory he was about to expound. Pseudo-pregnancy was a condition—depending upon the employment of sterilized males—in which the corpus luteum was present and acting in the same kind of way as in true pregnancy. From these experiments it appeared that when the corpus luteum reached a certain stage in its evolution changes took place similar to those at the advent of parturition, and extending even to the animal's habits and instincts—the rabbit, for example, beginning to make her nest. No evidence was forthcoming in this work that the ovary acted directly upon the uterus in promoting contraction, extracts of ovary had no specific effect at all, but, on the other hand, pituitary extract was found to have a specific effect upon the uterine muscle, thereby suggesting that the pituitary gland might be a factor in parturition. The experiments were then extended to some pregnant sows, in these also it was found invariably that the extract obtained from the ovaries was negative except at the very end of the 115 days' pregnancy, when it gave a markedly positive result. In the non-pregnant sow at about the time of oestrus the effects also were positive, but in the middle of the cycle, when the corpus luteum was fully developed in the ovaries, the effects were negative, as they were during the whole period of pregnancy except at the very end. This suggested an interesting interaction of the ovary and the pituitary and an interference of the corpus luteum. The theory seemed to follow—though it might be wrong—that the ovary worked through the pituitary, but that when there was an active corpus luteum present in the ovaries it so dominated the ovarian metabolism as to neutralize any pituitary effect. It was only at particular times when there was no corpus luteum in the ovaries, or only a non-active corpus luteum, that the ovarian secretion acted upon the pituitary, and this in turn upon the uterine muscle. This was the state of affairs obtained at about the time of parturition, and also at the time of oestrus, which explained why uterine contractions were to be observed in the menstrual cycle. The main objection to this theory was based on those cases in which the ovaries had been removed during pregnancy and the pregnancy had gone on. But very little was known as yet about the compensatory mechanism of the endocrine system, which might be of considerable importance. Ordinarily, for example, parturition was regulated by nervous mechanism, and yet it was known that nervous mechanism in parturition might be entirely dispensed with. Nobody disputed, again, that the thyroid gland had a definite function, and a belief in the function of the thyroid in respect to internal secretion was in no way upset by the fact that the thyroid could be removed in some cases without very much happening. Therefore he did not think that too much stress should be laid on this objection.

Professor Dixon added that not only had Dr Marshall, in the course of his experiments, made it clear that by removing the corpora lutea the animal was made to abort every time but it was also evident from the experimental work of numerous observers that if extract of corpora lutea were injected into animals over a prolonged period ovulation was inhibited. Professor Dixon showed some graphs illustrating experiments of his own bearing out the conclusions already put forward by Dr Marshall and demonstrating the effect of pituitary, or of something which acted in the same way, in the cerebro-spinal fluid. He recounted some observations of Meyer, who, in the case of ten women on whom Cæsarean section

had been done, had been able to make a lumbar puncture and extract cerebro-spinal fluid at this period, and, treating with this fluid other patients who showed uterine inertia, he had produced uterine contractions in eight cases and the normal birth of the child in four.

Dr WILFRED SHAW showed some microscopic sections illustrating the close resemblance between the corpus luteum in menstruation and in pregnancy. He said that one of the characteristics of the ovarian function was its periodicity. This applied, not only to the menstrual cycle, but also to pregnancy, it was quite common in the early months of pregnancy, on dates closely corresponding, to find small uterine haemorrhages taking place, and in the last months, eight weeks and four weeks before the commencement of labour, to have false labour pains. No explanation of this rhythm of ovarian activity had been given, but it was possible that the periodicity was related to the process of follicular ripening. If one assumed that follicular ripening was a rhythmical function of the ovary, one would expect the haemorrhages in early pregnancy as a result of the ripening and of the degeneration of a certain amount of tissue. Such haemorrhages hardly ever took place after the twelfth week, which was the time when the decidua capsularis fused with the decidua vera.

Dr W. LANGDON BROWN said he thought that everyone, however sceptical with regard to the pharmacological actions of extracts as indicative of gland function, would agree that these experiments meant something. It seemed that there was a chain of events by which the ovary stimulated the pituitary and the pituitary activated the uterus and the mammary gland, and that the corpus luteum could interfere with that sequence at almost any stage. It had been thought that the effect on the mammary gland was principally connected with the expulsion of milk by the contraction of the ducts, but it was difficult to see how, if that was all, the secretion could be kept up for two years, as he had known it in one case. It seemed to him clear that the line of work which Drs Marshall and Dixon had been pursuing ought to stimulate further study on the glycosurias and toxæmias of pregnancy. Dr MacLenzie Wallis had shown many graphs to prove that the glycosuria of pregnancy was a pituitary glycosuria. Was it due to the fact that the "hold up" which the corpus luteum ought to exercise was not taking place properly? With regard to the toxæmias of pregnancy, a good deal had been done on that point also. Not only was pituitrin directly antagonistic to insulin, but Coope of Liverpool had shown that a very important part pituitrin played in the transport of fat from the deposits to the liver. The overaction of pituitrin due to the failure of the corpus luteum to hold it might lead to the overtransport of fat into the liver, and at the same time pituitrin, antagonizing with insulin, would interfere with the glycogenic function, and so some toxæmias of pregnancy might develop.

Professor SWALE VINCENT said that he was not converted to the theory put forward that evening, though he agreed that any facts which were fully proved must mean something. At the same time, there might be views wide as the poles asunder as to what they did mean. He had been much interested in the development of this work, though he confessed that he had hoped to hear some further corroboration of the theory. The mere fact that a juice was extracted which had a certain pharmacological action did not necessarily throw any light on the function of the gland from which the extract was made, it meant simply that the juice had these pharmacological properties and nothing more. In the case of glands which it was believed had an internal secretion, the belief in this rested upon other evidence more important perhaps than the pharmacological.

Dr MARSHALL, in reply, said that Dr Shaw had put forward interesting evidence of the ripening of the follicles during pregnancy being responsible for subdued "heat" periods. It had been known for a long time past that in the mare one did get ripening of follicles at intervals after the beginning of pregnancy, and there were subdued "heat" periods in other pregnant animals. It was known also that abortion was likely to occur at particular periods, partly due to the loosening of attachments, but also possibly to some attempt at oestrus at that time.

Professor DIXON thought that the evidence was very clear with regard to the part played by the corpus luteum, because it was known what happened when it continued to exist and when it was removed. With regard to sugar tolerance and the influence of the pituitary, the work on this subject was continuing, and he had no doubt that very shortly the position set forth by Dr Langdon Brown would be made clear experimentally.

PROGRESS IN PSYCHIATRY

Dr P. H. COLE, physician for mental diseases, St Mary's Hospital, in his presidential address read before the Section of Psychiatry of the Royal Society of Medicine on November 10th, gave a review of the progress in psychiatry in his own time, and sketched the present trends of this branch of medicine.

In recalling changes and progress in the medical aspects of psychiatry, Dr Cole noted a recurrence to-day of many questions which were being raised in similar terms when psychiatry first claimed his attention thirty years ago. In Britain, Maudsley, Blandford, Hack Tuke, Savage, and Clouston were all then in active work. He had the good fortune during his early days to be closely associated with Maudsley, Mercier was commencing a steady output of valuable writings now too little studied, Crichton-Browne was already renowned as an orator, Clifford Allbutt became a member of the Lunacy Commission, and the present Lunacy Acts were coming into operation, not without some travail. Both psychiatry and psychology were on the eve of great developments. The French school was pushing hypnotism, and was sharply divided by Bernheim at Nancy and Charcot in Paris. The subject was very much to the fore at home, and was investigated by a committee of the British Medical Association. Its value was recognized when applied to hysteria, its study led to far-reaching results and acted as a stimulus to many who were confronted with mental phenomena that seemed to have little or no explanation. Among the difficulties the medical student of those days encountered in the study of psychiatry was the absence of systematic lectures and clinical demonstrations at many medical schools. As a consequence a medical officer took up an asylum appointment in ignorance of the mental maladies of patients he was to treat. Psychology was outside the scope of medicine. The older methods of introspection were being modified by experimental psychologists. The purely academic student still perused the writings of Mill, Spencer, and Sully, although the classical textbook of William James soon became the standard work. But psychology still seemed remote from human affairs and did little to assist the psychiatrist in his special study, and psychiatric science was almost sterile. Yet the accumulation of knowledge regarding the structure of the nervous system and its functions had been remarkable. Besides the work carried out on anatomical, physiological, embryological, and clinical lines, the comprehension of the autonomic system and its relation to the cerebro-spinal system, together with the functions and biochemistry of the endocrine glands, were engaging attention.

Among those who had made the most important advances in neuropathology in recent times the President recalled to memory the names of Hughlings Jackson, Flechsig, Mott, Bolton, Elliot Smith, Golgi, Gaskell, Langley, Sherrington, Head, and Pavlov. Sharpey-Schafer had taught much about the endocrines, while important work had been carried out by Orr and Rous on the path of infection in the nervous system by means of the lymphatics. Improved methods of staining had done much for histology, and the use of ultra violet rays in microscopy might yet teach more about the properties of the living cell. It must, however, be acknowledged that the mystery of mind was still unexplained and that its physical basis required more precise and exact knowledge to disarm criticism. The fresh psychological views had thrown new light on the mechanism of insane conduct and symptoms. The illuminating writings of Janet formed a landmark in the progress of psychiatry. Janet's conceptions of dissociation paved the way for the psycho-analytic movement initiated by Freud which had attracted followers all over the world. This movement had met with powerful opposition some of which was reflected in the establishment

of separate schools headed by Jung and Adler. Certain features of the work of Freud were worthy of careful notice, for besides being based on clinical observations it appeared to obtain biological confirmation. It had been claimed that the concept of primitive mental processes obeying the pleasure principle received some support when applied to child study, fairy tales, folk-lore, philology, and anthropology. Further, no work had done so much to attach meaning to the apparently meaningless symptoms of insanity.

Psychology used to be centred upon the cognition aspect of consciousness. The modern schools had moved the interest to the field of instinct, and psychology had been vitalized and brought into close relation to psychiatry. The work of McDougall, Rivers, and Trotter had contributed much to this desirable result. Psychology was now being applied to social as well as medical problems, as indicated by the instructive work on industrial psychology by C. S. Myers. And its application to other fields of inquiry was being sought, such as to the unrest in the political world, the change in religious beliefs, and the modern trends in art. But to psychiatrists the importance of the recent developments in psychology lay in a clearer understanding of psychopathology, psychotherapy, and the prevention of mental disease. Bernard Hart had done much to present the new psychology to the medical profession in a lucid and incisive style. The modern terms such as conflict, repression, projection, sublimation, transference, and *libido* were finding a permanent place in the literature of the mechanism of mind, although discussion concerning the nature and functions of the unconscious mind continued. It was not possible to speak with conviction as to the results of psychoanalysts. Their methods seemed of little use in the established psychoses, and there was little information available to determine whether in early cases or in psychoneurotics better results were obtained than from older methods of treatment. Yet psychoanalysis opened up fresh fields for research.

In the consideration of brain pathology the study of general paralysis best illustrated the progress made. Mott had taught the specific origin of paresis with a persistence and insight that was fully justified by the demonstration of the organism in the brain of a sufferer by Nogueira in 1911. Much fresh work was being accomplished concerning this disease, but many problems remained unsolved. Of late years the malarial treatment applied to suitable cases had introduced new hope. Noteworthy advances had been made in clinical conceptions of the psychoses, due mainly to the work of Krapelin, but a standardization of nomenclature was still very desirable. The institutional care and treatment of mental patients had received unemitting attention. There was less activity in building the immense institutions of the past, and asylums were daily becoming more hospitalized. The withdrawal of beer as a beverage had had a quieting and beneficial result in institutions. Alcohol was an etiological factor in 23 per cent of admissions in 1890, whereas it had fallen to less than half in 1920. Contact of the patient with the outer world was maintained more and more, and marked improvement in administration had taken place, including the reconstitution of dietary scales. The standard of mental nursing had progressed *pari passu* with the establishment of examinations and certificates, and occupation therapy was being developed further. Since the London County Council instituted its laboratories at Chisum, and at Denmark Hill much activity had been shown by workers throughout Britain. Heio Di Colo recalled the labors of Barin Lewis at Wakefield, the patient investigations of Ford Robertson in Scotland, and the centre at Cardiff under the energetic direction of Edwin Coodrill. Much more was being done by therapeutic measures based on scientific principles, and bed treatment for acute cases was now the rule. Two schools were striving for the ascendancy as regards treatment: the psychological laboured to prove the worth of psychotherapy, while the toxic searched for hidden sources of infection. Dr. Colo had been privileged to see the epoch-making work of his colleagues, Sir Almaroth Wright and his enthusiastic assistants—the pioneers of vaccine therapy—and he believed the clinical field of psychiatry must for the most part be held in common by both the psychogenic and physiogenic schools.

The teaching of psychiatry and psychology was of immense importance if progress was to be maintained. The medical practitioner still commenced his professional life with but a scanty knowledge of the mind in health and disease. But the advances lately made in the status and education of medical men entering the service of mental hospitals must be placed on record. Original research was now encouraged, study leave was granted, and the possession of a diploma or degree in psychological medicine was becoming necessary for promotion. The teaching of psychiatry in medical schools had made decided progress. The lecturer in this subject was now invariably on the staff of the hospital and had in out-patient department which the student could attend and see early cases of mental disorder, mental defectives, and psychoneurotics. Much had been written and spoken concerning the proposed clinics for the treatment of mental disorders, which no doubt would do much to speed up early treatment in psychiatry. A parallel movement was the desire of many to obtain power to allow voluntary patients to enter rate-aided institutions. Both proposals deserved whole-hearted support, for the clinics would help to bring this specialty into closer touch with general medicine, and existing mental hospitals would still further increase their hospital character and lose the invariable element of detention which so diminished their prestige and value. From the study of recent statistics Dr. Colo believed that the recovery rate of patients in mental hospitals compared favourably with that of patients in general hospitals. An afternoon spent in the out-patient department of a large general hospital revealed a high incidence of chronic disease. While so much was designed for the curable, let them not proceed too far and segregate the so-called chronic patient anywhere and anyhow, remembering also a mistake in prognosis was apt to occur and recovery sometimes took place after a period of many years.

The President next passed to psychiatry and the law. Prison doctors were now required to have a knowledge of psychological medicine, and criminology was making considerable advance. The criminal responsibility of the insane was still a matter of contention between the medical and legal professions. The recent Atkin report upholding the M'Naghten rules did not satisfy psychiatrists. Defect of reason should not be the sole governing factor in establishing irresponsibility for crime. It was, he held, a mistaken notion that the doctrine of psychological determinism might absolve a person from the consequences of his actions. The tenets of medical men and psychologists did not differ from those of their fellow citizens in regard to the necessity for primitive measures. But the criterion of insanity in criminal cases should be established by fresh methods to be abreast of modern knowledge. There were other differences also between the legal and medical professions, and doctors were undoubtedly hindered in their work by existing legislation. In this respect they had welcomed the advent of the Royal Commission, and hoped that real progress would result from its labours. The public attitude towards psychiatry also required consideration. It was disappointing to find a recent leader in a highly respectable daily journal referring to the devoted men who have laboured for psychiatry in the past as "keepers of mad-houses." Such an expression applied to the memories of a Maudsley or a Meigs could only reflect a deplorable ignorance on the part of educated public opinion. A recent novel by a distinguished author dealt with the adventures of an elderly psychotic finally admitted to a mental hospital. The descriptions and the unfavourable shown with existing conditions indicated the want of sympathy and understanding shown by the general public towards the psychiatric physician and his work. Yet both articles and novels hostile though they might be in some respects were portents of a growing concern for the welfare of the insane. In view of this widespread public interest, the first step should be to insist that insanity was no strange plague that struck down without reason or warning, that from the "shell-shocked" soldier to the maniac of popular imagination there was but a difference of degree, that both suffered from mental disorder and for both there was a good hope of amelioration and cure. Psychiatrists wanted co-operation, financial aid for research, generous contributions to the funds of mental

institutions, and, above all, the trust that had happily been given to medical men in every other branch of practice. With the progress that had been made Dr. Cole felt the future could be regarded with hope.

PLASTIC OPERATIONS IN THE REGION OF THE EYE

The Sections of Ophthalmology and Surgery of the Royal Society of Medicine combined for a discussion on November 13th on plastic operations on the face in the region of the eye. Sir ARNOLD LAWSON presided. All the speakers showed lantern slide photographs of their cases, and much of the time was occupied by describing in detail, with the aid of these illustrations, the nature of the disfiguring condition and the measures taken for its repair.

Mr H. S. SOUTER, in opening, said that he spoke as a general surgeon, one or two of whose methods might perhaps be of interest to the ophthalmic specialist. A good many years ago Dr. Bequaert of the London Hospital began to send him a number of cases of hairy moles, which frequently presented very extensive surfaces. He did not at first realize the real difficulty in treating these cases. It was comparatively easy to deal with a hairy mole which did not come into the neighbourhood of the eye, but when the mole reached up close to the eye the operation became difficult and delicate. He had treated these cases—all except one of them being cases of children—by the am-flap method. In children it was easy, by throwing the arm up above the head, to apply to the face a turn-up flap from the upper part of the chest or shoulder, and thereby to replace very large areas of skin. The child remained bound up in this condition, with the head, as it were, buried in the arm, for about a week. He felt confident that if a considerable amount of skin was wanted for plastic surgery of the face in a child—it was different in an adult—this method would be found the most satisfactory in its results. But the arm should be so arranged as to leave a certain space between the arm surface and the cheek. The difficulty in dealing with hairy moles in the neighbourhood of the eye arose on account of ectropion. His practice was to leave a little of the mole in the corner of the eye, and afterwards, when he had got his graft, to excise that small remaining portion and put in a Thiersch graft. In this way any danger of ectropion was avoided. The results in these cases were very good, and, generally, with a little powder, no permanent disfigurement was noticeable. In one adult case he showed how, the patient having been left without an eyebrow as a result of excision, he swung down a piece of hairy mole from the forehead to take the place of the eyebrow, and the difference was not easily discernible. In adults generally, he thought, the tubular flap was preferable, though he had done the am flap in one instance. He also showed a cutaneous ulcer which had developed on lupus of the face in a young woman, which he had treated by dissecting out the ulcerated area and replacing it with a graft from the arm so that the disfigurement was scarcely to be noticed.

Mr A. W. ORMOND recounted the considerable variety of procedures available in ophthalmic surgery to meet different conditions. He illustrated in particular the method he used, in the case of destroyed eyelids, for forming an eyelid from the ordinary pedicle flap. Long pedunculated flaps might be obtained from a distance, and, in favourable situations, successfully grafted, but homoplastic grafts were rarely successful, whereas autoplasties might be and often were quite satisfactory. The problem of dealing with a contracted socket in which an artificial eye was to be placed was one of the most difficult in plastic surgery, and not very often successfully overcome. It involved repeated operations and the exercise of much patience, on the part of both surgeon and patient. The technique of Thiersch grafting was important. A large flap knife, with a blade one inch or more deep, should be used, the knife and the skin should be kept moist with sterilized normal saline, the skin should be maintained taut by an assistant, and the knife used as horizontally as possible. In con-

sidering which of the many procedures should be used in a given case various points had to be kept in mind, but not the least important was the length of time involved in carrying out one method or another and the number of operations it would be necessary to perform. The necessity of a long stay in hospital and the psychological effect of repeated operations and of enforced inactivity sometimes reacted unfavourably on the patient's mental outlook. The surgeon should not look upon these cases as presenting fascinating problems for the exercise of his skill, but should have regard to all the patient's circumstances, which sometimes might indicate a procedure stopping short of the cosmetic result which would be attained if treatment were further prolonged.

Mr T. P. KILMER described a procedure for replacing lost eyebrows. He had learned from a considerable experience of cases of burns that eyebrows had very definite functions, apart from their cosmetic value. They shaded the eye from the sun, they acted as sweat collectors, and they protected from wind. Eyebrows might be made by means of Wolff or whole-thickness grafts of hair-bearing skin taken from the scalp. Care must be shown, of course, in choosing an area in which the hair is growing in the right direction, and it was rather interesting to speculate whether a piece of hair-bearing scalp which would become bald at its original site would retain its hair-bearing properties when transferred to the eyebrow region.

Mr G. H. POOLEY described some cases in which repair had been undertaken for the extensive loss of skin due to surgical removal of tumours, or to burning with molten metals, or to septic conditions. Plastic operations could be performed fairly quickly on cases which were surgically clean, but in cases in which there was sepsis it was advisable to wait twelve months or so until everything had quietened down and all sepsis had disappeared before attempting to do plastic operations, otherwise the sepsis lighted up again. He found that the best results were given by a large flap on a wide pedicle. It should be rather pressed into the space instead of stretched across. He got as much subcutaneous tissue as possible to avoid any hollow or tunnel at the edge of the flap and the skin. A large flap taken from the temporal and frontal region, just at the junction of the hairy scalp and the forehead, he found most satisfactory. Care should be taken to hold the flap exactly in place during dressings in order that the little vessels which were forming might not be broken down again. In cases of extensive burning with molten metal, resulting in a very large adhesion of the lower eyelid to the corner, he found it useful to divide freely and to put in a piece of india-rubber tissue with a suture through it, leaving it in for many weeks until all the cut tissue had healed quite soundly and the epithelium had grown over it, and then to remove the india rubber.

Mr J. J. McINTOSH showed some pictures illustrating the results in trauma in the region of the eye, treated at the Queen's Hospital for Facial Injuries, Sidcup, also in a number of pathological conditions. He insisted that the shrunken socket was really a much greater deformity than no socket at all, and therefore in some cases of war injury under his care it was decided to remove the socket altogether and skin it over. He had done this operation also in civil life under certain indications—for example, in a coal miner who had lost his eye in an explosion, and who, if the socket had been left as it was, would have been subject to constant irritation from coal dust. If one was not going to get definitely a good result in the socket it was better to skin it over completely.

Mr M. W. B. OLIVER showed a number of diagrams illustrating the methods of reconstruction of eyelids. He could not agree with Mr. Pooley that as much subcutaneous tissue as possible should be taken, for, in reconstructing the lower eyelid particularly, it was important to avoid making it look too bulky. He laid stress also on the need for removing the whole of the conjunctiva and the whole of the orbital tissue to obtain a proper epithelial inlay. Most important of all was the cutting of the skin graft. The mould must be covered with one single skin graft, with any gaps there was almost certain to be failure.

Mr A. EDWARDS said that the cases which had interested him were mostly those of rodent ulcer in the neighbourhood of the eye, and he had always felt that where it was possible to excise the growth and replace it by a sliding flap, that was the method to choose. There were, of course, cases in which that could not be done, and the very beautiful results shown by Mr Souttar could not have been obtained by such a method. Most of the cases of rodent ulcer that came to him were cases in which radium and x rays had failed, incidentally it was rather a reproach that those who gave radiological treatment did not seem to know when they were beaten. If radium was going to succeed at all it succeeded fairly early, and if such early success was not forthcoming it was of no use at all going on with the radium treatment of the case. The method of making sliding flaps was somewhat difficult in practice, but it was infinitely more difficult to describe because the surgeon did it more or less by instinct. With regard to artificial eyes, he found that a mould painted in very low tones, as if the eye were in shadow, was superior to the ordinary artificial eye, and if the patient wore "spectacles of the American pattern" the result was not conspicuous.

The CHAIRMAN then threw open the meeting to general discussion, but although there was a crowded attendance only one member spoke, Mr HARRISON BUTLER, who remarked that for holding Thiersch skin-grafts he preferred dental wax to stent, because it remained soft and answered the purpose very much better, it was well to oil the razor when cutting the graft.

MYOMECTOMY FOR FIBROIDS

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on November 5th, the President, Mr T. G. STEVENS, in the chair, Mr VICTOR BONNEY read a paper on myomectomy as the treatment of election for uterine fibroids.

Mr Bonney contended that conservation of the uterus should be the ideal aimed at by the surgeon whenever the uterus, apart from the fibroids, was reasonably healthy. He reported a new series of 120 consecutive myomectomies performed by him in the last three years. A single tumour was removed from the uterus in 47 of these cases, in the remaining 73 the tumours removed were multiple, the greatest number enucleated at one operation being 80. The successful removal of so large a number was rendered possible by the use of the clamp invented by him which, when applied over the lower uterine segment, simultaneously compressed both uterine arteries, so that if the ovarian vessels were compressed by ring forceps the operation became practically bloodless. This was an immense gain, for it rendered many myomectomies possible which previously were impossible. In applying the clamp both round ligaments, as well as the lower uterine segment, must be included in its grasp. He referred to the paper on myomectomy read by him before the Section three years ago and recalled the general technique of the operation that he then described. In the new series of 120 myomectomies he had had 3 deaths, and in his first series of 100 cases 2 deaths, so that the operative mortality for the 220 operations was 2.2 per cent. The difficulties of the operation, as practised on a wholesale scale, would be largely circumvented by the experience accruing from increasingly widespread adoption. It had been objected that new fibroids would probably develop subsequent to the operation, but this was a bogey. It had also been objected that menorrhagia might persist in spite of the removal of the tumours, but this was equally unlikely. He had never yet had to operate a second time on any of his patients for continuance or reappearance of excessive bleeding. It had been argued that the uterus from which a number of fibroids had been removed would be functionally useless. This also proved to be fantastic. A number of the women on whom he had operated had subsequently become pregnant, and the idea that the conserved organ would probably be an incubus to its

possessor could be dismissed. Mr Bonney illustrated the beneficent possibilities of the operation by describing cases in which, in spite of the presence of a large number of tumours, or of tumours in difficult situations, he had been able to send the patient home, not only cured, but whole and normal. This was an enormous improvement compared with hysterectomy, in which the removal of the tumours was counterbalanced by the loss of an organ which had other uses besides that of child-bearing. The removal of the uterus inflicted on most women a severe psychological injury. The aim of all treatment should be, not merely to remove disease, but to leave the patient normal, and any method which failed to achieve this end was obviously second-rate. It was now possible in practically every case of fibroids to conserve the uterus, and myomectomy should therefore be regarded as the treatment of election for these tumours. He hoped to see the time when every surgeon called upon to operate for that condition would enter upon his task with that conception in the forefront of his mind.

Dr ARTHUR GILES said he was convinced that myomectomy was a valuable operation, and that it was probably not used as often as it might be. He had always been greatly interested in the operation, which he had first employed in 1899, and he had so far performed 203 myomectomies, with 3 deaths. He differed from Mr Bonney mainly as to the scope of the operation, and considered that it was seldom advisable in patients over 40 years of age. The chief aim of the operation was to preserve the uterus for child-bearing, and when this was virtually out of the question the purpose of the operation was gone. It could be admitted that the uterus had some influence over the ovaries, but after the age of 40 this was unimportant. His desire to limit the scope of myomectomy was based on several considerations: first, the question of mortality. Mr Bonney recorded 5 deaths in 220 cases, a mortality of 2.2 per cent, and said that the mortality of hysterectomy was 2.5 per cent. He could not agree to such a high figure for hysterectomy, in his last 1,000 hysterectomies for benign conditions there were 6 deaths, a mortality of 0.6 per cent. Then there was the question of recurrence. If every seedling fibroid was removed during a myomectomy the chance of recurrence was very small, but this would involve microscopic examination of the uterus, and though Mr Bonney might have no records of recurrence it was quite possible that he would meet with some when more time had elapsed. Dr Giles felt strongly, therefore, that when child-bearing was out of the question hysterectomy was the better operation. As to myomectomy during pregnancy, he had seen 18 cases, one patient miscarried, but the others went on to full term. From one patient who went to term he removed ten fibroids. He had never had occasion, however, to remove the pregnancy as well as the fibroids, the whole object of the operation was to preserve the pregnancy, and consequently, if there was any likelihood that the operation would entail the sacrifice of the foetus, he would prefer to wait and perform a Caesarean section at term, dealing with the fibroids at the same time.

Mr GORDON LUKER remarked on the importance of the conservative treatment of fibroids during pregnancy, rest and sedatives were nearly always effective in relieving symptoms. Operative treatment was but rarely indicated owing to the risk of sacrificing the pregnancy, as actually happened in one of Mr Bonney's cases.

The PRESIDENT confirmed and augmented the previous speaker's remarks on conservative treatment during pregnancy.

Lady BARRETT agreed as to the great importance of performing myomectomy instead of hysterectomy where a healthy uterus could be conserved. She did not understand, however, why it should be necessary to interfere with an existing pregnancy when myomectomy was required. The removal of numerous seedling myomata seemed an unnecessary prolongation of the operation, for she had found in seeing for microscopic myomata that they occurred more commonly in uteri containing multiple seedling tumours—especially in women of 30 to 36 years of age—and these presumably would grow later.

Mr VICTOR BONNEY, in reply, said that in spite of many fortunate runs of luck, the general operative mortality of

hysterectomy in hospitals did not differ much from that which he had recorded for myomectomy. In regard to pregnancy complicated by fibroids, he agreed that only a proportion of these cases required operative treatment, and of these it was possible in a good many to remove the fibroids and leave the pregnancy. Where, however, a large number of tumours were present, or the tumour was unfavourably situated, it was absolutely necessary to remove the pregnancy with the tumours. He strongly deprecated the harsh view that the uterus was merely of use for child-bearing. Anyone who said so had no knowledge of women as women, but merely as cases.

Origin of the Lutein Cells

Dr WILFRED SHAW, in a communication on the lutein cells of the corpus luteum, said that their origin had for long been disputed. At present two theories held the field, that of von Baer, who attributed the origin of the lutein cells to the theca interna layer, and that of Bischoff who held the granulosa cells responsible. In view of the vast amount of work done on this subject in different fields, the problem must now be considered from a very broad aspect. In the rabbit and mouse ovulation occurred at a fixed time after copulation. A graduated series of specimens could therefore be obtained showing corpora lutea at various stages of development. This technique, first employed by Sabott, showed that in the mouse and rabbit the lutein cells were derived from the granulosa layer. Later, Marshall confirmed this in sheep. Van der Stricht, working with the ovaries of the bat, showed that, besides the large lutein cells, another series of cells could be seen, at the periphery and in the hills of the convolutions, they were much smaller and less numerous than the large lutein cells. Van der Stricht had demonstrated these cells in the human corpus luteum, and his observations were confirmed by Bohler, Seitz, and others. The term "para-lutein cells" had been applied to them by Pinto and American authors. The cells had been found in some fifty specimens of corpora lutea that Dr Shaw had examined, and it seemed clear that in the corpus luteum two types of cell were represented. There was no reason to believe that the para-lutein cells were early forms of the large lutein cells, so it must be assumed that they had a different origin. As there was no evidence that the theca externa cells underwent luteinization, the structure of the mature corpus luteum suggested that the theca interna cells developed into para-lutein cells and that the granulosa cells gave rise to the large lutein cells. This view was borne out by the results of methods of differential staining. Dr Shaw added that the problem of the origin of the large lutein cells of the human corpus luteum would be solved with mathematical accuracy if a reliable series of young specimens of known date was available. Such specimens were rarely obtained, and at present one could only give the results of investigations of isolated specimens. He had obtained, so far, eight specimens of young proliferating corpora lutea—the oldest corresponding to the nineteenth day of the menstrual cycle. These showed the mode of development of the corpus luteum from the follicle after ovulation. The outstanding feature of the early forms was the hypertrophy of the cells of the granulosa layer. These cells soon attained a great size, and because of the denseness of the surrounding stroma proliferated centrifugally. Further early specimens showed the convoluted outline characteristic of the mature corpus luteum. The theca interna cells did not proliferate or hypertrophy beyond the state they had reached when ovulation occurred, and in these early specimens the two layers could be easily identified because of the great difference in size between the two sets of cells. The study of this series of young corpora lutea indicated clearly that the theca interna cells became the para-lutein cells of the mature corpus luteum, and that the granulosa cells gave rise to the large lutein cells.

Specimens

The President, Mr T G STEVENS, showed a specimen of fibromyoma of the uterus, weighing 47 lb 5 oz, removed from a woman aged 59.

The patient was known to have had an abdominal tumour for twenty years, but had refused operative treatment as long as she could get about. When brought to him she was suffering from an abdominal tumour which hung down to about the middle of her thighs, she was short of breath and had oedema of both

legs. She could only walk when held up by two persons, and then with a tottering gait. An apparatus consisting of a block and tackle was rigged up over the operating table with four large metal hooks attached, which were fixed into the tumour so that it could be pulled up and held in position during removal. Subtotal hysterectomy was performed through an 18 inch incision, the apparatus worked perfectly and eliminated any mechanical difficulties. The patient made a good recovery, and five months later was reported to be learning to walk again. The tumour proved to be a single fibromyoma containing a few small cystic cavities. There were no important degenerative changes.

Mr STEVENS also showed a specimen of a large "cystic tumour of the liver simulating an ovarian cyst."

The patient had had the menopause two years previously, and her only complaint was enlargement of the abdomen with a little pain for about six months. The tumour was about the size of a twenty-eight weeks' pregnancy and occupied the greater part of the abdomen. It seemed to consist of two parts, one resting on the pelvic brim and the other felt under the left epigastric region. The consistency of the tumour was that of a multilocular ovarian cyst. The patient was wasted. The diagnosis of an ovarian cyst was made, and owing to the wasting of the patient and the peculiarity of the upper tumour it was thought that the larger mass was a malignant growth and the upper mass perhaps a secondary growth in the omentum. Operation was performed at St Mary's Hospital on October 6th. The upper tumour was found to be a ruptured portion of the lower tumour originating in the left lobe of the liver. The tumour had no pelvic connexions, and examination of the pelvic organs showed the uterus, tubes and ovaries to be small and atrophied. There were numerous adhesions to the inferior surface of the omentum. After ligature of these adhesions the tumour was excised from the liver. Macroscopically it was soft containing large numbers of spaces, the result of necrosis. Microscopically it had the structure of a sarcoma composed of uniform spindle cells arranged in a structureless matrix without any fibrillated connective tissue.

Mr W McCULLAGH said that a specimen had been shown by him at the society in January last, by permission of Dr C H Roberts, whose case it was. The tumour had a similar appearance and connexions at the exploratory laparotomy, it was a columnar-celled carcinoma arising from the gall bladder. The patient was 57 years of age, and had been sent in as a case of twisted or malignant ovarian cyst.

Dr R DONALDSON said that a few days previously he had received for examination a tumour of similar appearance, removed by Mr Ivor Bael, who found it attached by a thin, short pedicle to the greater curvature of the stomach. There were no adhesions.

Mr D W ROY and Dr R DONALDSON showed microscopic sections of a case of early endometrioma of the Fallopian tube, discovered in the course of subtotal hysterectomy for fibromyomata of the uterus.

XEROPHTHALMIA

A MEETING of the Newcastle-upon-Tyne and Northern Counties Medical Society was held in the Royal Victoria Infirmary, Newcastle, on November 5th, Dr NEIL MACLEOD presiding, when Mr J S ARKLE read a paper entitled "Xerophthalmia, a vitamin deficiency disease."

Mr ARKLE dealt with the condition as it presented itself to an ophthalmic surgeon, observing that it was to him, rather than to the physician, that these patients usually went for advice and treatment. Yet it had to be recognized that local treatment in itself was insufficient, and for a proper understanding of the disease the underlying nutritional factor must be taken into account. Except in times of great distress, it was an uncommon disease, but in such a town as Newcastle, under the present industrial conditions, its incidence in the eye department of a large general hospital was about six or seven cases a year. The clinical work of Bloch of Copenhagen, and the experimental work of Osborne and Mendel, had established that the disease was due to an absence from the diet of a sufficient quantity of a certain specific substance present in milk, butter, egg yolk, fat, and cod-liver oil. In all probability this substance was the necessary food factor "fat-soluble A." The practical clinical point arising from this was that where the nature of the disease was recognized treatment could only be effective when the errors in diet were corrected, if no dietary correction was made local treatment with lotions and ointment would have no effect. If the condition were allowed to progress a more or less extensive ulceration of the cornea would ensue, followed by keratomalacia, and in some cases blindness. The chief

point in the recognition of kerophthalmia was the dryness of the conjunctivae, which became wrinkled and shrunken. Later on small yellowish-white spots were formed, giving the conjunctivae the appearance of having been spotted with paraffin wax. At a still later stage the dryness spread over the whole conjunctivae and over the cornea, which was then dull and hazy or greyish in appearance. These changes were well seen in two cases shown to the society that night.

Treatment of Lobar Pneumonia

Dr H S BROWN, in a paper on the treatment of lobar pneumonia in general practice, dealt first with the special difficulties in treatment met with in the small houses of the working classes, where the majority of their cases were to be seen. The difficulties were the fixed prejudices of the relatives against allowing fresh air into the rooms, even when the rooms were so built as to admit it, and the absence of skilled nursing. Good nursing with poor doctoring was more valuable than poor nursing with good doctoring. After reflecting on his experience of this type of case which gave most difficulty, he had decided that the practitioner should try to assess as early as possible the patient's physical capacity to withstand the infection, and to review this day by day during the progress of the illness, in the same way as an estimate of the fighting chances of a boxer in the prize ring might be made. Careful attention should be given to the patient's previous state of health and history, to the condition of his heart, and to his blood pressure. If the fighting chances appeared good, the medical practitioner's attitude was one of inactivity until symptoms appeared, when, if severe, stimulant treatment should be instituted early, it should not be withheld as a form of extreme unction until heart failure was imminent. Local applications were only useful when there was pain. The drugs he had found most useful were digitalis and strychnine, opium and morphine were valuable during the first three days of the illness in sleepless patients to conserve their strength. At one period he had given an extended trial to vaccines as a form of treatment, without being able to arrive at any definite conclusion as to their value. The most he could say was that if vaccine treatment was started early it appeared to shorten the acute illness, although followed by a slower convalescence and recovery.

Clinical Cases

Dr R A BOLAN showed a group of cases of lupus vulgaris illustrating the improvement after treatment by general irradiation from ultra violet rays and carbon arc lamps. Dr GEORGE HALL showed a case of bronchiectasis after hipiodol injections and a ray examination, also a case of parenchymatous nephritis occurring in a man during a recessive period of lymphadenoma. Mr N HOPKINSON showed a case of calcified adenoma of the thyroid with toxic symptoms. Dr D WELLS PATTERSON showed a case of recent acute anterior poliomyelitis in a boy aged 16, where the paralytic condition had arisen without any prodromal illness or symptoms. Dr N R RAWSON showed a case of micromelia with absence of the arms, and radiograms and photographs to illustrate this and kindred conditions. Dr J C SPENCE showed (1) a case of idioglossia to indicate the improvement that could be attained by visual demonstration to the patient of methods of speech, and (2) cases of congenital hypertrophic stenosis in infants after and during medical treatment, with charts demonstrating the value of atropine treatment. Mr G GREY TURNER presented (1) Two cases of cleft palate illustrating functional and aesthetic recovery after operation. One was a child, six years after operation in infancy, with almost normal speech and articulation, the other was a woman, aged 29, two years after operation for complete cleft palate, with great improvement. (2) Two cases ten and eleven years after excision of the rectum for carcinoma, both patients now in good health. The character of the growth had been determined microscopically, and specimens of the tumours were shown with the cures. (3) Two cases after successful transplantation of the ureters into the rectum for ectopia vesicae. Both patients were now well, one was aged 7, three and a half years after the operation, the other, aged 21, four years after operation. In neither case was there any evidence of impairment of renal function. One patient had subsequently had a second operation for osteotomy. Mr A HEDLEY WHITE showed a case of acute osteomyelitis of the tibia in a boy after operative treatment and the use of hipp dressings. There was complete healing with removal of the sutures after four dressings.

Reviews.

TAYLOR AND POULTON'S "MEDICINE"

THE late Sir Frederick Taylor's *Practice of Medicine* first appeared in 1890, two years before Osler's *Principles and Practice*, the tenth edition of which was noticed in our columns on October 31st. Both these popular textbooks are now in editions brought out by pupils of the original authors and are admirable in every respect. Comparison of the first with this edition¹ shows that Taylor's *Medicine* has been transformed in size, get-up, pages, and, of course, in matter, and that the present volume differs from the last (the twelfth) edition in containing eighty more pages and double the number of plates, of which eight are coloured, the number of radiograms being increased from nineteen to thirty-six. The coloured plates show the retina in arterio-sclerosis and parenchymatous nephritis, normal and abnormal blood cells, and nucleated red cells, and in addition sixteen of the commoner skin diseases are depicted on four coloured plates. The plates representing the cells of the blood are most successful and should be of great use to the reader. Another and a welcome change is that, as far as possible, the text has been kept clear from the names of authorities and references, which have been collected to form a list at the end of each section. These lists are not long and have been specially chosen from two points of view to provide means of verifying statements about which doubt may arise in the readers' minds, and to indicate fuller reviews of the subjects with bibliographies.

Among the fifteen new articles there is a short summary of melioidosis, a rare infection resembling glanders and due to *Bacterium whittmorei*, which is closely allied to *B. mallei*. The section on metabolism and diseases of the endocrine glands contains several additions and a monogram showing the relation between basal metabolism, age, and weight. Dr H W BARBER has largely rewritten the account of the diseases of the skin, and Dr C P SYMONDS has made a number of changes in the text of the diseases of the nervous system. That revision has been thoroughly up to date is shown by an appendix on the etiology of malignant neoplasms, in which Gie and Barnard's recent discovery of an ultra-microscopic virus and a specific factor is described.

In conclusion, Dr POULTON and his assistants, Dr C P SYMONDS and Dr H W BARBER, should be heartily congratulated on the improvements in this well known textbook.

RENAL VASCULAR DISEASE

Dr F M ALLEN, who is so widely known in connexion with the investigation and treatment of diabetes mellitus, writes from the Physiatric Institute, Morristown, New Jersey, on the *Treatment of Kidney Diseases and High Blood Pressure*. Part I, described as a *Practical Manual for Physicians and Patients*,² is now published, Part II, dealing with "questions of anatomy, pathology, renal function tests, and other complex or obscure problems of etiology," is delayed pending the completion of some investigation now in progress. The proceeds of this publication and of the author's practice will be devoted to the support of the Physiatric Institute, the adjectival description of which made the reviewer look at the printed word more than once, and of the researches undertaken there. Though the lay reader will doubtless be impressed by parts of this work, such as the high death rate of renal circulatory diseases, which in America far exceeds that due to any other cause, and was responsible for the deaths of the last two Presidents of the United States, there is much that he is unlikely to understand, for the author seems sometimes to forget the double character of his audience.

There is a great deal of interesting material in this handbook, especially the view expressed on the deleterious action of ordinary table salt which is regarded as both raising

¹ Taylor's *Practice of Medicine*. Thirteenth edition. By F. P. Poulton and F. M. Allen. London: The Physiatric Institute, 1925. (Pp. 810.)

² *Treatment of Kidney Diseases and High Blood Pressure*. By Frederick M. Allen. Part I. *Practical Manual for Physicians and Patients*. Morristown, N.J.: The Physiatric Institute, 1925. (10s. 8vo pp. 210.)

the blood pressure and acting as an irritant to damaged kidneys, for in addition to causing oedema salt may induce changes in size of the capillary endothelium and spasm of the arterioles.

In the discussion of the etiology of renal-vascular disease a number of factors, such as intestinal auto-intoxication, endocrine disorder, the wear and tear of modern life, emotional disturbance and worry, are practically ruled out. Infection is not regarded as a proved cause of high blood pressure or of arterio-sclerosis, though it is admitted that there are some strong arguments in favour of this view, and in the section on prophylaxis the prevention and removal of focal infections are recommended. That excessive protein feeding has an evil influence Dr. Allen agrees, but not with the wholehearted enthusiasm with which he condemns excess of sodium chloride. The dogmatic pronouncement, "One central fact seems to be that hypertension never exists with normal kidneys," is at once qualified by the admission that "even in rather severe and long-standing hypertension the renal lesions may be limited to such slight changes in the small arteries that only close study reveals them." The significance of these slight changes in the small renal arteries, especially in late middle life, should have received some attention before summarily controverting the late Sir Clifford Allbutt's conception of hyperpiesia, to whom and to which no reference is made, indeed, to British eyes Dr. Allen may appear a little inclined to plough his native furrow to the exclusion of others.

In discussing protein restriction the practitioner is advised to regulate the diet according to the percentage of blood urea, and it is stated that, while in critical emergencies, such as severe acute nephritis or a chronic case with an excessively high blood urea and imminent uraemia, a diet containing no protein or only the small quantities present in fruits and some vegetables may be used, it is regarded as a temporary expedient to be limited to a week or two at most. The term "pseudo uraemia" is employed for all the cases usually described as uraemia in which the blood urea is not raised, and "muscle oedema" is, after Widal, described as a condition of sodium chloride retention disproportionate to the water retention, "often overlooked by physicians." The great majority of patients stand restriction of salt to 0.3 gram daily indefinitely, but a few show serious symptoms of salt deficiency, which can be diagnosed by their rapid relief after the ingestion of 2 grams of sodium chloride. The principles of diet are discussed at some length, recipes and menus are given in detail, and the use of drugs is critically considered, not without flashes of humour, as, for example, in saying that the much advertised yeast treatment has as its chief merit its harmlessness, and otherwise "is merely a faith cure created by printer's ink."

PSYCHOTHERAPY

In a volume entitled *Principles of Psychotherapy* Professor PIERRE JANET summarizes the evolution of the various methods of mental treatment, pointing out their historical origin, outlines the laws on which the various therapies are based, and indicates the conditions under which such methods of treatment can be applied with reasonable chances of success.

The author believes that the term "psychotherapy" should be used in a much less restricted sense than is usual. Most definitions suggest that it should be confined to those methods which provoke psychological reactions simply and directly, but, as Janet points out, in our efforts to change a man's behaviour we cannot make a radical division between what is mental and what is physical. Our advice is given by means of words which involve physical phenomena just as a man's behaviour involves movements as well as ideas. Changes also of routine, cathartics, sedative or stimulating substances have both a physical and mental action. He goes on to show that from a more general point of view there is a question whether it is possible to make an exact division between physiological and psychological functions. Neuropathic disorders are the expression of the activity of the whole organism, its growth, its evolution,

its involution. The organs and functions that take part in these phenomena are not well understood, their disorders are scarcely suspected, but they exist, and must be given more and more study. Psychology is not independent of physiology, but it demands a more delicate and profound physiology than that of respiration or of digestion. The study of mental diseases cannot do without medical and physiological information, on the contrary, it will demand increasingly a much more thorough medicine and physiology. The treatment of these diseases, far from being possible after brief medical study, will fall to the most accomplished clinician, and will require the use of all forms of examination and all the most delicate methods. All treatments of this kind should be, so Janet considers, included under the term "psychotherapy"—anything, in short, which exerts a favourable influence upon disturbances of mind and behaviour.

As might be expected in view of the distinction and wide experience of its author, this volume contains much excellent advice on the treatment of psychoneurotic patients, and will well repay careful study.

COLLECTED PAPERS OF THE MAYO CLINIC

THE sixteenth volume of the *Collected Papers of the Mayo Clinic and the Mayo Foundation*,⁴ edited by Mrs M. H. MERRITT, is a complete record of all the papers issued during 1924 from this energetic centre, some are given in full, others abridged or abstracted, making up a total of 165, there are 27 others mentioned by title only. There are no fewer than 160 contributors, the Mayo brothers are each responsible for 13 papers, Dr F. A. Willis for 15, and Dr Melvin S. Henderson for 8. The articles are arranged under the nine heads of the alimentary canal, urogenital organs, ductless glands, blood and circulatory organs, skin and syphilis, head, trunk, and extremities, brain, spinal cord and nerves, technique, and miscellaneous. The last contains the largest number of articles (44), some being general addresses, such as Dr L. B. Wilson's, rather intriguingly entitled "Necropsies as an index of efficiency of treatment," in which he states that in the United States of America necropsies are performed on probably not more than 2 per cent of all fatal cases, and expresses a grave doubt if "an internist, however skilled, can maintain a high degree of efficiency with a low percentage of necropsies." The first two papers in this section are of rather special interest, they are by Dr E. C. Rosenow, and deal with focal infection and elective localization, and on a precipitating and neutralizing semilabral antistreptococcus horse serum.

In the section on the ductless glands, Dr L. G. Rowntree's contribution on Addison's disease shows that the Munherd system of treatment, so called after a medical man thus treated at the Mayo Clinic, has been employed in eleven other patients, seven of whom are living. The principle of the treatment is forced organotherapy—namely, frequent administration of epinephrin hypodermically and by the rectum, and of the whole gland or adrenal cortex by the mouth to the point of tolerance, which varies widely in individuals and therefore has to be determined in each case in order to settle the proper dose. Writing on the treatment of epidemic encephalitis, Dr J. B. Doyle mentions that out of 130 patients treated by Dr E. C. Rosenow with his streptococcal vaccine, 85 improved and 43 did not show any change, and expresses the opinion that no reliable data for determining the efficacy of vaccine therapy are available. Among the thirty-nine papers in the section devoted to the alimentary canal, which occupies one-fifth of the volume, there are about a dozen on peptic ulcer, and two valuable papers by Dr F. C. Mann and his co-workers on the physiology of the liver as elucidated by total removal of that organ.

This collection of papers is a valuable source of reference, and inspires sincere admiration for the Mayo Foundation and its beneficent influence on medical research.

⁴ *Collected Papers of the Mayo Clinic and the Mayo Foundation*. Edited by Mrs M. H. Merritt. Vol. XVI. 1924. Published May 1925. Philadelphia and London: W. B. Saunders and Co. 1925. (Med 8vo pp viii + 131. 25s. 6d. net.)

THE MEANING OF SYMPTOMS

A RECENT addition to the series of small volumes with the general heading "To-day and To-morrow," written by some of the most distinguished English thinkers, is entitled *Pygmalion, or the Doctor of the Future*. The relationship between title and subtitle is not solved until near the end of the homily, when the author, Dr R. McNAM WILSON (who dedicates his book to the memory of Sir James Mackenzie), says that he looks forward to the time when the practitioner of medicine, "like Pygmalion, will look on his work and see, not disease and death, but the glowing lineaments of life." The author believes that a very simple, but nevertheless new, medical idea is slowly making its influence felt. This idea challenges the belief that "a symptom is a sign of disease." The correct definition is that a symptom is an expression of "inadequate reaction to life." "It may be suggested that every stimulus is lethal, a potential death-blow." "Every failure to react completely is a failure to recover completely from the blows by which Nature chastises us for our good." "On the other hand, without stimulation there can be no reaction." Here, says Dr Wilson, is a paradox man must struggle all his life to overcome circumstance and condition, yet could not live at all if these adversaries were to cease to trouble him. The thesis of inadequate reaction is illustrated by cases. Thus a man is giddy and exhausted after receiving a shock, or a glutton who has eaten too freely experiences a pain in his stomach. "These people are reacting normally to violent stimulations." Their symptoms cannot be accepted as signs of disease. Then we have the case of the man with a great pain in the region of the stomach. He was treated without success for gastric catarrh, apparently by a doctor of the past. Then the doctor of the present gave the patient a scientific bismuth meal examination, with negative results. So the man was told that his pain was imaginary. Unfortunately the doctor of the future did not get an opportunity of dealing with the case, the patient wanted glasses, went to an ordinary present-day ophthalmic surgeon, and found that his stomach trouble was miraculously cured by spectacles. The doctor of the future, for whom a symptom means a reaction to life, would have directed his attention to any circumstance tending to exaggerate the force of stimuli—that is, tending to put the individual in a false position towards his environment. From all this it appears that the doctor of the future is not altogether unlike the capable doctor of the past, for whom, as in Dr Wilson's ideal, the science of medicine was "the science of life, of humanity."

With the not unfamiliar statement that "the age of materialism is past, with its dull and deadening influence," and a quotation from Wordsworth that we should "Learn by a mortal longing to ascend towards a higher object," Dr Wilson closes his book. What it is all about we are not quite sure, but we may readily agree with Dr Wilson that the doctor of the future should be a humanist, a cultured man ripe in intellectual attainments, not lacking in emotional sympathy, a lover of arts as well as a student of the sciences.

SMOKE ABATEMENT

It is satisfactory to find evidence of a renewal of interest in smoke abatement. The subject was very much alive about a quarter of a century ago, when something was done, but public interest soon afterwards died away. Last July four societies—the Society of Chemical Industry, the Institution of Chemical Engineers and Gas Engineers, and the Midland Institute of Mining Engineers—held a conference at Leeds, at which a number of papers were read, but there was not time for any full discussion. The conference was therefore adjourned, to meet again in Sheffield on November 20th, and arrangements are being made for another conference in February in Manchester. Further evidence of the growing interest of the subject is afforded by the fact that after an interval of thirteen years a

second and much enlarged edition of the book by Dr J. B. COHEN, professor of organic chemistry at Leeds, and Dr A. G. RUSTON, entitled *Smoke: A Study of Town Air*,⁶ has been published. The evidence which Professor Cohen and his collaborators have published in scientific journals and collected here has been a valuable aid in the campaign for smoke abatement. Their main interest has not been the health question, but the damage done by soot and coal smoke to vegetation and in the disintegration of the stonework of ancient buildings, on these aspects of the problem it has been possible to collect more precise evidence than can be furnished by medical statistics. This second edition contains a new section on the plant as an index of smoke pollution. The book is illustrated with twelve striking photographs depicting the damage done by smoke to vegetation and public buildings.

Dr W. VERNOR SINCLAIR's little book on *Combustion and Atmosphere and their Relation to Disease*⁷ is a brief but strongly worded condemnation of the evils of a smoke-polluted atmosphere. The subject is treated in an elementary fashion, and to some assertions a word or two of explanation or qualification might be looked for by the thoughtful reader. But there is surprisingly little exaggeration or controversial matter, and the book will prove very useful in awakening greater interest in the question of the pollution of the atmosphere.

KENYA

In his book on *Kenya*⁸ Dr NORMAN LEYS, who spent some years in medical service in East Africa, purports to describe the conditions of life in the colony and the sociological problems it presents for solution for the benefit of European readers. Beginning with a brief historical and general survey, in which he lays stress on the debilitating effect of many of the widespread chronic infectious diseases that are the bane of native energy and progress in Tropical Africa, he gives in the second chapter a brief account of native life in East Africa as he knew it some years ago. Comparing village life in Africa with village life in England, he finds the former superior in a surprisingly large number of particulars. The remaining fourteen chapters of the book are written, so far as the reader may judge, with the object of proving the uniformly disastrous results on the native of European settlement in the colony. To readers who do not know East Africa Dr Leys will no doubt appear perfectly successful in his effort, but those who have some acquaintance with the facts of life in Kenya will notice many misstatements and sins of omission. Thus, to quote a few out of many, in his chapter on "Recent history," Dr Leys, while seeking to show that the natives have been dispossessed of an unduly large proportion of the agricultural land in Kenya Colony, states that it includes "a desert that covers nearly 200,000 square miles out of a total area of 240,000" (p. 67). In the recently published volume⁹ and maps by Shantz and Marbut it is shown that there is no desert, properly so called, in Kenya Colony, and only a comparatively small area of semi-desert shrub. Most of the area described by Dr Leys as "desert" is mapped by Shantz and Marbut as acacia savanna, with a definite and often high agricultural value, and a rainfall for the most part over 20 inches a year. It is not easy to understand in what sense such land can correctly be described as "desert." The same fault vitiates three of the maps given by Dr Leys on pp. 106, 107, in which large (and variable) areas of the Masai reserve are labelled "desert", yet these areas are described by Shantz and Marbut as composed of acacia savanna, mountain grassland of high value as pasture, and thorn forest. To describe as "desert" a large area of the reserve given

⁶ *Smoke: A Study of Town Air*. By J. B. Cohen, Ph.D. B.Sc. F.R.S. and Arthur G. Ruston, B.A. D.Sc. New and enlarged edition (second). London: E. Arnold and Co. 1925. (Demy 8vo pp. xi + 103 14 plates. 6s. 6d. net.)

⁷ *Combustion and Atmosphere and their Relation to Disease*. By W. Vernor Sinclair, L.R.C.P. I.R.C.S.E. London: J. Bale Sons and Daniel on Ltd. 1925. (Cr. 8vo pp. 47. 2s. net.)

⁸ *Kenya*. By Norman Leys, M.B. D.P.H. With an introduction by Prof. or Gilbert Murray. London: 1 and 1 Woolf. The Hogarth Press. 1924. (Demy 8vo pp. 410. 1 map. 15s. net.)

⁹ *The Vegetation and Soils of Africa*. By H. L. Shantz and C. F. Marbut. New York: 1923.

⁵ *Pygmalion or the Doctor of the Future*. By R. McNam Wilson, M.B. Ch.B. London: Hegan Paul Trench Trubner and Co. Ltd. New York: E. P. Dutton and Co. 1925. (Fcap. 8vo pp. 71. 2s. 6d. net.)

to the Masai for the grazing of their cattle is misleading. Throughout the volume Dr. Leys shows a certain unhappy eagerness to blacken the character of the white settlers in Kenya Colony, that is best illustrated, perhaps, in his chapter on "Black and White." Here he sets out at length two cases in which Europeans were accused of causing the death of natives, in each instance he records the case for the prosecution but omits all mention of the evidence for the defence. How is it possible in such a manner to give a fair picture of what occurred in these instances? Professor GILBERT MURRAY, President of the League of Nations Union, who writes an introduction, says in it that the attempted humanization of the existing world order embodied in the Covenant of the League of Nations implies that the advanced races of mankind have definitely accepted the task of governing and guiding in their own interests, those peoples which are "not yet able to stand by themselves under the strenuous conditions of the modern world." He questions whether there is "a single mandatory Power in which the preponderant political forces can be kept true to the spirit of this treaty except by constant vigilance and unsparring criticism." Great Britain, as compared with most other nations, he considers, has, on the whole, in these matters a creditable record, but he believes there is a real and dangerous opposition between average colonial opinion, based on knowledge of the facts and daily intercourse with black people, and public opinion at home, sentimental, disinterested, and genuinely anxious for justice, but grievously crippled by ignorance and lack of understanding. Dr. Leys, he thinks, has "the power of possibly helping these two opposites to understand one another." Professor MURRAY continues, "The rule of black by white appears to be, for the present time, an absolute necessity." He therefore seems disposed to accept the view that the native races are not yet fit for the equality before the law desired by Dr. Leys.

Dr. Leys's information about the colony is not up to date, and it seems likely that a visit to Kenya would do much to correct many of his misapprehensions. However harsh may be the judgement of Dr. Leys on the Kenya settlers, at any rate he shares with the majority of them a real affection for the native population, and this must be counted the chief virtue of his book.

MEDICAL FOLLIES

PRACTITIONERS of the cult of osteopathy are moving heaven and earth, and the House of Commons, to grant them an official register in order (it is said) that the public may be protected from unqualified osteopathic imitators. The time is opportune, therefore, for reviewing *The Medical Follies*,¹⁰ a book by Dr. MORRIS FISHBEIN, Editor of the *Journal of the American Medical Association*, from which we have quoted on two occasions lately. Starting with Elisha Perkins, an American, who in 1796 produced Perkins's patent tractors to draw disease from the body, Dr. Fishbein describes the origin and history of homoeopathy, osteopathy, chiropractic, and the electronic reactions of Abrams. There are also chapters on the antivivisectionists, health legislation, physical culture, birth control, and rejuvenation. In his introduction Dr. Fishbein compares the medicine man of the savage tribe with the leaders of modern medical cults. Both have the habit of believing themselves to be divinely inspired, both have some mental or physical peculiarity, or a "magnetic personality," both are students of the psychology of their patients, understand the importance of the fundamental urge of sex, and realize that a strong claim is far more convincing than a weak one if neither can be proved. It is through neglecting this last characteristic that Dr. Fishbein thinks apparently that osteopathy will come to grief, and that chiropractic will "engulf its mother organism." The better sort of modern practitioners of osteopathy have thrown over a great many of the claims of their founder, Andrew Still, and are endeavouring to make the faith into something resembling the actual practice of medicine. Throughout the book there are many acute observations on the state of mind of the followers of the various cults. Thus "Learned persons with one-track

minds can always be found who will endorse the most ridiculous hoaxes-poems in matters of health." "Credulity is not limited to any single class. There is a pride of learning and accomplishment that is more dangerous than the most abject ignorance." Dr. Fishbein cultivates his pages with amusing stories, such as that of the nine clergymen who told lion Elisha Perkins's tractors brought them relief, while one of the clergymen found "them also useful in picking walnuts." He records how the great-grandfather of Andrew Still, who "flung to the breeze the banner of osteopathy," came from England to Buncombe County in North Carolina, an irrelevant fact, says Dr. Fishbein, cited merely because of the name of the county. It appears also that Andrew Still's brother James, a clergyman, thought at first that Andrew was crazy. Andrew hoped that James's brain would ripen in time, so he let him pray until at the end of eighteen years James said "Hallelujah, Drew, you are right, there is money in it, and I want to study osteopathy." Despite these cynical touches, Dr. Fishbein gives credit where he can. "Perhaps," he says, "osteopathy has taught us something by its stress on massage perhaps even Iddism has made itself valuable by showing the value of suggestion in conditions affecting the mind." But chiropractic and Abramsism he cannot endure, they "teach only the ease with which delusions may be foisted on the public."

A NEW BOOK OF CHILD CARE AND PROTECTION

THE second edition of *The International Year Book of Child Care and Protection*¹¹ has recently been published for the Save the Children Fund of London. It has been compiled, as was the first edition (1924) by Mr. LEONARD FURMAN, the editor of *The World's Children*.

The book gives a record of State and voluntary effort for the welfare of the child, including information on marriage, divorce, illegitimacy, education, the care of the destitute child, treatment of juvenile delinquents and conditions of juvenile employment throughout the world. In the preface written by the Marchioness of Aberdeen and Temair she commends the book to the attention of the public, now aroused to the recognition of the claims of childhood.

It is a valuable book of reference, and represents an enormous amount of work in collecting data from all parts of the world. At the beginning of the book is an index to new and projected legislation and other developments since the first edition. The countries are again arranged in alphabetical order, but the "Whos Who" section has been omitted, and in its place is provided a useful international bibliography of works on child care and protection, and of periodicals bearing on the subject. The chapters on Roman Catholic and Mohammedan law have been abridged, but an interesting chapter on Hebrew law by Dr. W. M. Feldman has been added. In his introduction the compiler makes a plea for reform in the demography of child welfare, and expresses the hope that *pari passu* with the development of technical aspects of work for the care, protection and education of the world's children, the question of developing a common international system of recording at least the more essential statistics will engage the attention of Governments and of international bodies and conferences competent to deal with it.

NOTES ON BOOKS

IN the BRITISH MEDICAL JOURNAL of May 16th, 1925, we published, under the title "Lister, the Investigator and Surgeon," an abridged version of the first Lister Memorial Lecture, delivered before the Royal College of Surgeons of England, by Sir WILLIAM WATSON CHEYNE, Bt. The full text of the lecture has now been published in book form, with a portrait of Lister as frontispiece and an appendix.¹² In his brief preface Sir Watson Cheyne explains that his wish had been to give a short history of Lister's work, but that was impossible in a single lecture. Hence the lecture was first

¹¹ *The International Year Book of Child Care and Protection* Compiled by Edward Fuller from official sources. Second edition. London: Longman, Green and Co. and The World's Children, Ltd. 1925. (Cr 8vo, pp. vi + 565, 7s. 6d. net.)

¹² *Lister and His Achievement*. By Sir Wm. Watson Cheyne, F.R.C.S. London: F.R.C.S. etc. London: Longmans, Green and Co. 1925. (Demy 8vo, pp. 136, 1 portrait, 7s. 6d. net.)

¹⁰ *The Medical Follies*. By Morris Fishbein, M.D. Second edition. New York and Liveright. 1925. (Cr 8vo, pp. 223, 2 dollars.)

written out in full and afterwards compressed. The lighter portions, illustrating Lister's character and the general plan of his work, formed the lecture as delivered, the remaining more detailed account of his work and investigations (together with some personal experiences and opinions of the lecturer) have now been incorporated in the appendix. The former occupies the first 38 pages, and the latter 92 pages, the remaining 6 pages contain the index. The whole, now bearing the title, *Lister and His Achievement*, forms a worthy tribute to the master by his chief disciple. It only remains to add that the book is excellently printed and appropriately bound, with a gilt medallion portrait in profile on the cover, inscribed "Joseph Lister, 1827-1912."

In simple and easily understood language Mr D. WARD CUTLER, chief protozoologist to the Rothamsted Experimental Station, Harpenden, presents the results of modern research on *Evolution, Heredity, and Variation*.¹³ There is, of course, much about Charles Darwin, the greatest of all naturalists, who was born in 1809, the same year as Gladstone, Chopin, Mendelssohn, Oliver Wendell Holmes, and many other famous men, and was himself an example of the inheritance of high intellectual powers. Mendelism is clearly explained, and the predominant influence of heredity is firmly insisted upon. Professor Pearson and the late Professor Doncaster being quoted to prove that the kind of mind that the child will have is irrevocably decided before birth. This leads to the late Professor Doncaster's conclusion that although eugenic measures are as yet hardly within the range of practical politics, there can be little doubt that the nation which first puts them into practice will in a short time be the leader of the world. On the question of the transmission of acquired characters, which is of considerable interest from a medical point of view, Mr Cutler takes the orthodox biologists' position that quite apart from the absence of any known definite physiological process by which body changes could be transmitted to the nuclei of the germ cells, other evidence in support of the transmission of acquired characters is unsatisfactory, as it can always be interpreted in more than one sense, or is of an indirect nature.

The leading paper in the new number of *Brain*¹⁴ is that by Stanley Barnes and E. Weston Hurst on hepatolenticular degeneration, a condition first described by S. A. K. Wilson in *Brain* in 1912 under the title "progressive lenticular degeneration." Four new cases are recorded, and the conclusion is reached that Wilson's condition should be grouped with Gowers's "tetanoid chorea," certain cases of "pseudo scleriosis," and Thomsen's torsion spasm. The authors state that nervous symptoms of the disease never occur until the liver has been grossly damaged, and they believe that the toxin producing the attacks of acute hepatitis which cause the cirrhosis has a bacterial origin in the alimentary canal. The number also contains several other papers and some short notices on recent publications.

Professor H. STANLEY ALLEN's monograph on *Photo Electricity* deals with a subject that is of increasing importance to the physicist, and has practical applications in the sphere of work of the physiologist, the photographer, and the radio telegraphist. The characteristic feature of photo electric action is defined as the loss of a negative electric charge or the gain of a positive electric charge under the influence of light, which is traced to the emission of negative electrons from the illuminated surface. From the experimental point of view investigation of the subject presents a most complex affair, as great variations in the activity are found to result from trifling changes in the experimental conditions. Professor Allen goes into the whole subject very fully, he gives a large number of references to the original literature, and has brought this, the second edition of his book, very well up to date. His chapter on the physiological effects of photo electricity, including photo therapy and the photo electric theory of vision, is particularly interesting to medical men, the author concludes that "although a full explanation of colour vision is still wanting, the correct theory, when it is found, will be a photo electric one, the number of electrons liberated determining the intensity of the sensation and their velocity the quality or colour of the light perceived." The more immediately practical or commercial applications of the photo electric cell, an apparatus for the measurement or control of radiation, may,

he believes, lead to the production of a rival of the thermionic valve in wireless work. The book is well written, and may be recommended to experimentalists and readers interested in the subject with which it deals.

Professor MARTIN PAPPENHEIM's book has been translated into English by Mr. GEORGE CAFFEY, and published under the title *Lumbar Puncture*.¹⁵ It is based on many years of teaching in the neurological department of the University of Vienna, and deals with the anatomical and physiological relations and technique of lumbar puncture, with methods of investigation of the cerebro spinal fluid, and with the diagnostic and therapeutic applications of this test. It contains an appendix on encephalography and puncture of the cisterna. The practical character of the book and its insistence on details of technique make it a valuable exposition of the subject for both student and practitioner.

Physiotherapy in General Practice,¹⁶ by Dr. E. BELLIS CLAYTON, is intended for the use of general practitioners and to be a guide to massenses. The book describes treatment by massage, exercise, radiant heat, and the faradic and galvanic current, the descriptions being based on the methods in use at King's College Hospital. A valuable introductory chapter gives a short explanation of massage, electrical treatment, and medical exercises, this introduction will be useful to readers unfamiliar with the specialized forms of treatment dealt with in the later chapters. We note also a second commendable feature in the appendix, wherein certain medical gymnastic terms and exercises are briefly explained.

Mr. BRADLEY PATTEN's *Early Embryology of the Chick*¹⁷ is a handy book for students beginning the study of embryology. It is clearly written and well illustrated and explains very well questions which students often find difficult to understand, such as the establishment of the yolk sac, amnion, and allantois. The book carries the development of the chick only to the fourth day of incubation of the egg. Here the story comes to an abrupt end, and this will seriously diminish its utility for medical students in particular, who need to know more about the later stages of development. The addition of even one more chapter giving a brief account of further stages in development would have added greatly to the general usefulness of the book.

The book on methods of gas analysis,¹⁸ by Dr. WILHELM KLEIN and MARIA STEUBER, is a short one, but contains a careful account of the various methods of analysing the inspired and expired air in metabolic research. The authors are assistants at the Landwirtschaftlichen Hochschule in Berlin, where the study of the respiratory exchange has been pursued for many years. Much of our present knowledge of this subject we owe to this institution. The authors give full descriptions, accompanied by diagrams, of all the types of apparatus in common use. The technique of respiratory gas analysis has been worked out to a high degree of perfection, and we here find the advantages and disadvantages of the different types of apparatus minutely discussed. The book concludes with a series of useful tables of constants for making the numerous corrections necessary. Any person working on the respiratory exchange will find this book a very useful laboratory manual.

We referred on October 24th (p. 762) to the fourth of the Henderson Trust Lectures,¹⁹ which was given by Professor WILLIAM W. GRAVES, at Edinburgh, on October 16th. This lecture has now been published and may be obtained from Messrs. Oliver and Boyd.

Dr. J. SABRAZES, in collaboration with J. V. PRADE, has written a small book²⁰ on diaphragmatic hernias. The detailed history of a single patient forms the nucleus of the book, and paves the way for a consideration of the plural effusions that not infrequently supervene in this type of case.

THE PRESENT STATE OF THE TEACHING AND PRACTICE OF SURGERY

BY

SIR G. LENTHAL CHEATLE, KCB, FRCS,
SURGEON TO KING'S COLLEGE HOSPITAL

DURING the last year I had a heart-to-heart talk with a learned and thoughtful provincial surgeon. Among the things he said to me were the following: "Provincial surgeons no longer look to wards the surgeons of London for new notions of leadership, and this is because there is little or no original research work being done by London men. Provincial surgeons see as much surgery, operate on as many patients, and we are technically as perfect as London men." Gentlemen, although I would not hear you enemy say so, we have all had some such thoughts about ourselves.

Research Work

Let us begin with the first point he made—that London is losing its leadership, because so very few men are engaged in research work as well as practice. I think it must be admitted that, in these days, mere technical ability is not enough to maintain ascendancy of leadership, or to regain ascendancy if leadership be lost. I take it to be a fact all the world over that he who is only a so-called clinical surgeon and nothing more is losing, or has lost, his position as a leader in his profession. He can add very little knowledge, and except for acquiring skill in the technicality of his art he can acquire very little more of any value whatever. His thoughts can never be profound, and without research work there is very little encouragement for him to think at all, instead of his teaching being inspired by the results of his own original research, it is limited in outlook, dull and conventional in type.

It seems to me essential that every surgeon should be performing research work, however little, in a laboratory, however small, in conjunction with his practice. I know many men will say that practice excludes the possibility of such a scheme. I do not admit this. Time can always be found for things that a man wants to do. It will be said that some men are more fit for practice than investigation. I do not think that statement has been properly tested. But that is not so much my point. My point does not concern those men. They can never be leaders in their profession, however great their practice, or however high may be the social position of their patients. It is the men who aspire to leadership who should come back into the fold of original research as well as surgical practice.

That some men are fitted only for investigation is another point to consider. This statement is yet another instance of one that is made without proof. Besides, supposing that kind of man does exist, I am not talking about him. My point is that a surgeon will never "cut any ice" as a leader unless he does research work as well as being technically perfect in his art. Research work and technical perfection are not in opposition. Nearly all parts of research work are concerned with delicate manipulative processes, experiments on animals are pure clinical work, and such experiments would naturally help the worker in his operations on patients. It may also be said that doctors can be investigators by research work applied only at the bedside, and that great work in the past has been performed by this method. That, taken alone, is no longer possible. A man must have the backing of his own research laboratory work.

How research work leads from one thing to another is borne out by a conversation I had with a student the other day. When I advised him to start original investigation by cutting sections, at different ages, of skin wounds that had healed by first intention, he said, "What's the good of that? Surely everything is known about that." Well now, that student was wrong. Six months' work at that particular observation, provided he be a more enthusiastic and intelligent student than the one I have just mentioned, would make him now more about it than anybody else of his year. It would compel him to study the

healing of wounds in all the other tissues besides the skin, it would lead him into the study of controlled hyperplasia and the study of internal secretions. It would entice him into a study of uncontrolled hyperplasia and take him into the regions of tumour formation generally. Apart from that, the whole question of infection and the prevention and cure of infection would come under his research. At the end of a few years he would find himself, provided he had ordinary enthusiasm and intelligence, an authority on the subjects with which he was dealing. Supposing such a man, in the course of his study, came across a simple statement like this: "Malignant ulcers of the stomach commonly arise from simple ulcers." If he were to accept the main teaching of the present day, he would say, "Simple ulcers of the stomach commonly become malignant."

But such a man as I have described would not accept what others say on important questions of this kind, and the question is important, because it is said that simple ulcers of the stomach become malignant they ought to be excised by partial gastrectomy—a very serious operation. One of the first things he would say would be, "Let me investigate the pathological evidence on which is founded the statement that simple ulcers of the stomach commonly become malignant." He would find, on this evidence, two things: that ulcers excised as being simple were really extensive carcinomatous ones, and that ulcers which had been removed and reported on as early carcinomatous were not carcinomatous at all, but simple ulcers in which some epithelial cells were dislocated—a state of things with which he would be perfectly familiar in his examinations of many wounds that heal by first intention, and would regard it as a state of things that does not necessarily prove malignancy. He would also be perfectly aware that in other tissues which are healing—take, for example, the formation of bone round the healing of a simple fracture—bone tissue may appear in an abnormal situation, but it is not necessarily in an osteosarcomatous state. I would agree with his conclusions: that there is no pathological evidence to support the notion that malignant ulcers of the stomach commonly complicate a previously benign one.

Again, I think a man with this training would not be tempted to scrape the inside out of a uterus to see if he were dealing with uterine carcinoma. He would appreciate the fact, from his studies of uncontrolled growth, that one of the surest ways of inducing the spread of carcinoma is to open fresh lymphatic spaces and thereby transplant carcinomatous cells, and that a man who does this kind of preliminary examination is spreading disease before he removes it. Again I would agree with him. I would further suggest that all the discharge from a suspicious uterus should be collected, centrifugized, and the deposit cut in paraffin sections and stained and then examined. Dr. Ewing, of the Memorial Hospital, New York, pointed out to me the danger of this process, and the examination of the uterine discharges was also his suggestion.

The research worker, besides collecting data of this kind, perfects his own work and is also leading others to perfect theirs. During what appears to be unimportant research work, at any moment a fact may arise of epoch-making importance. Although it may be a genius who succeeds in recognizing it as being a fundamental fact, there is no harm in a man giving himself a chance of showing the world he is a genius. Original work is so interesting. It keeps the mind of the researcher alert, young, and thoughtful. His teaching is more inspired and gives to his listeners notions and facts that cannot be found in books. It is wonderful to note the immediate response of his students when they hear something of the teacher's own work and his views. It makes them think with him on matters relating thereto, and often those matters are the only ones which cause men to come after a lecture is over to ask questions.

The other day I was listening to Dr. Bigg in the Memorial Hospital of New York demonstrate some of his most recent work. Roughly speaking, it was this: He took a healthy strain of mice, mated them, and on the birth of the litters immediately separated them from the mothers so that no suckling took place. He re-mated

* Presidential address (abridged) delivered before the Section of Surgery of the Royal Society of Medicine, October 21st, 1925.

NOV 21, 1925]

THE TEACHING AND PRACTICE OF SURGERY

[THE FIRST & SECOND MEDICAL JOURNALS] 959

these mothers at once, and the next litter was treated in the same way. Of these mothers 87 per cent developed fulminating carcinoma of the breast. The same results occurred after he ligated the mammary ducts on one side, and allowed the litters to suckle the other side. Carcinoma developed in the ligated breasts. That is a very dramatic experiment. Miss Maud Sly puts the whole matter on one side as being a question of heredity. Bagg himself considers it is a question of stagnation of irritating contents that induces carcinoma. Dr Gye would say that "neither Miss Maud Sly nor Bagg has taken into sufficient consideration the presence of the ultramicroscopic organisms and a specific factor." To which Bagg might reply, "Supposing I grant the presence of the breasts of these organisms and a specific factor in the breasts of these carcinomatous mice, it cannot be concerned that 87 per cent of them would have suffered from this fulminating carcinoma had I not treated them in the way I did. Therefore, supposing Gye be right, I may have proved that there is another factor essential to the action of the organism and the specific factor—namely, preparation of the epithelial cells." To which Gye might again reply, "You have not shown that to be an essential addition to my theory. I expect what you have really done is to make the specific factor more active." That is the line of research I humbly suggested to Dr Bagg.

There are no boundaries to the researcher's ambition, of all surgeons who aspire to leadership. I do beg compared with the micro surgical technical expert I do beg practice to work hard at original research. I would refer my audience to the first paragraph of Sir William Leishman's address which he delivered to the War Section of the Royal Society of Medicine on October 12th. He said

"At the outset it is my purpose if I can, to remove from your minds the impression that research is of necessity an sterile matter confined to mysterious laboratories and that it can be carried out only by professors and specialists who have given years of work to their subject who are a 'peculiar folk' and talk in a tongue not understood of the people. It is true that much experimental inquiry demands expert knowledge, special equipment, and comes within the opportunity of comparatively few of us, but I prefer to give to the word 'research' a much wider significance and to take it to cover any means by which we, of set purpose and on a deliberate plan, strive to add to our existing knowledge of the case, the prevention and the treatment of disease. I have on more than one occasion spoken on this subject and have urged in connection with it a far closer collaboration for this purpose between clinician and specialist than exists at present."

The Unit System

The great hope in the future that London will regain its position of leadership, and prevent its surgery from degenerating into mere practice, lies, I believe, in the encouragement given to research by the unit system of teaching. It may be said that trial has been made of this system and in many instances it has been a failure. Against that it must be admitted that there are instances of great success, and there are instances where it is promising to be successful. It must be recognized that they are part of a new scheme, and time is required for their directors to grope about and discover the best arrangements that can be made for research and for teaching. I sincerely hope that those bodies who are placing money at the disposal of these units will not be discouraged by want of immediate return in the shape of striking discoveries, and so forth. Money cannot subsidize genius, but it can, and I feel sure will, create a body of men more capable of leading in their profession than any body of men that has existed in the past, and in due course genius will come along.

What a wonderful, envious position the directors of these units occupy! Take only one example, which to me is of greater importance than is usually attached to it—namely, the skilled assistance which a director can always insist upon having in his surgical operations as well as in his research. Take a surgeon at a teaching hospital, who is not a director of a unit. His assistant is a house surgeon who only begins to be useful as an assistant at the expiration of his office, when the poor surgeon has again to start

with raw material. The same surgeon with skilled assistance works like an angel, but in his hospital, where everything should be the best from a showman's and teacher's points of view, you will see him working like a good man struggling with adversity. This is a more important question than that of merely a showman's or teacher's. Perfect assistance halves the length of an operation and lowers mortality, and, in fact, sometimes the hospital surgeon dare not undertake an operation with the unskilled assistance he has at his disposal.

Also it seems to me that a director of a unit should be allowed private practice, which would render him a more human, tactful soul, a better teacher, a better operator, and make him the possessor of a more complete conception of a surgeon's duties to all classes of men. The permission to practise would increase the number of men from which a director could be selected. As the teaching hospitals are now opening their doors to paying patients, I can see no reason why the director of a surgical unit should not operate upon his private as well as his hospital patients in the same institution, and thus save time for his unit duties. The directors of units are complaining that there is so much administration to be done that they have no time for original work of their own. A powerful man like the director of a unit could insist upon having someone under him who could take this part of his labours off his hands.

Specialties

I began my address with the conversation I had with the provincial surgeon. That morning he performed the following operations. He operated upon two patients suffering from gastric ulcer, completely removed two fibroid uteri, from a fifth patient removed a kidney that was a mere sac containing calculi, and finally he plated an ununited fracture of the tibia. The histories and examinations of these patients were complete in every detail, and his assistance was perfect. He had himself cystoscopically examined his renal patient. He had observed urine coming from the one kidney, and an absence of urine from the cystoscopic examination for himself, for no other man in his town was capable of doing so. This fact shows that practice made him—a general surgeon—efficient in what is a urological specialty in London. In London general surgeons do not get these patients. Therefore they have no practice in efficient urological examination.

The work of my provincial surgeon proves the absurdity of the contention that only specialists can efficiently examine urological patients. This leads me on to my next point. In addition to our negligence in appreciating the importance of original research, another great cause of the atrophy of surgery is the breaking up of its practice into various and completely unnecessary specialties. The system is wrong in principle, and is proving wrong in practice. It is wrong in principle because Nature does not specialize. She governs her dominions on large general principles, which she applies to different tissues of the body. Specialists are doing the opposite. They are studying as best they can minute portions of the human anatomy, and thereby too often lose sight of great guiding principles.

For example, infection and biochemical changes are forces that hit all tissues, and to study their respective or united effects on only a small part of the human anatomy excludes the possibility of a comprehensive view of their actions on all the other tissues as well, unless two or three more specialists are brought into consultation. It is proving wrong in practice. The men who practise the different specialties are consciously and unconsciously recognizing the error of their limited occupations.

The specialists of the new generation are gradually including parts of the body other than those to which they were originally limited. A modern gynaecologist operates on everything connected with the female, unless it be a cerebral lesion. I cannot see anything that is excluded by the modern orthopaedic surgeon, and the modern urologist appears to be gradually claiming all the surgical diseases that affect the male in the same way as a modern gynaecologist is claiming all the diseases that affect the female. Even the modern laryngologist is beginning to include within his

ambit diseases that are extra-laryngeal—such as goitre, carcinoma of the tongue, and the glands of the neck—and thus he appears to be encroaching on the realm of the modern gynaecologists and urologists.

However amusing and interesting it may be to watch, I regard this tendency of different specialties to widen their spheres of action as being all to the good. It is destructive to a bad system. At present, if I were to advise a man what to do if he wanted to become a general surgeon, I should advise him to take up at least one of the four specialties I have mentioned, for there is nothing to stop a man from taking up a specialty and performing operations on any part of the body. I congratulate that man for the reason I have given. He will help to stop a bad system. Hence the question I would like to ask, "Why break up surgery into specialties that are becoming only names, and which have no physiological, pathological, or technical reasons for their existence?" I am glad to say that the forces that control this great society clearly see this. I would like to encourage these forces that recognize the error of our ways, by suggesting that a committee be formed to consider the whole problem and to discover means by which the separation into specialties can be stopped, and to encourage more meetings of the whole society to hear new important notions that deal with new interests, no matter who the man is who provides such material. I would let any man, however young or however old, with a new notion well worked out, utter his message before the whole society rather than before a little part of it. There are many papers read before sections that would profoundly interest the whole society, but they are now lost and hidden away from general knowledge. We should get to know each other's work better, and be able to judge with what manner of man we are dealing and the value of his message.

Decentralization of Surgery

At the outset I particularly want it to be understood that I do not criticize any set of men, and that what I say refers only to the question of supplying the public with the best surgical treatment.

There can be no doubt there is a great, increasing, and perfectly reasonable demand on the part of the public for surgical aid that should be available near at hand. The diseases that call for urgent and immediate surgical attention compel the recognition of the fact that surgery must be as near the patient as possible.

Again, the volume of surgical patients who are not suffering from urgent and acute disease is so enormous that it cannot always be attended to from the great centres. Hence surgery is undergoing a great decentralization, which cannot and should not be stopped. In the numerous hospitals that have been established within a radius of thirty miles of London local men are operating three or four times a week. Inside and outside this radius general practitioners are forming groups that continue in operating partner, while in London itself the demand is greater than can be supplied by the hospitals attached to teaching schools. Large suburban hospitals have been built which have been staffed by surgeons of first-rate calibre, in fact, the reputations of these surgeons is so secure that these hospitals can be no longer regarded as mainly nurseries for men whose ambition is to be attached to their teaching schools. Lastly, the local infirmaries are opening their doors to surgical patients of all kinds, and often are obliged to admit patients for whom there is no room in the teaching hospitals.

Hence it is essential that the public in all areas should receive the best surgical aid, and the schools must supply it with surgeons whose knowledge, judgement, experience, and technique are second to none. It follows as a natural sequence of events that men who are operating in the hospitals of the decentralized areas must be also competing successfully in the private practices of those who taught them. Hence the economic state of the teachers becomes a momentous matter that has to be met and settled. The old system is obsolete, and the worst of it is that the old system is the present one. It must not go on indefinitely, for many unfortunate things will happen to the public if it be not supplied by the best surgical practice.

Let me inquire what is the economic state of these teachers at the present time, say, in London. It is impossible to describe in words that meet the situation, it is so obviously un sound. They are receiving no money for their hospital and teaching services, and they are considerably out of pocket in giving them. They are teaching the very men who are successfully competing with them for the money upon which they live.

In comparatively recent times surgeons required kudos by being attached to teaching schools. They treated the private patients who are now being generally treated in the decentralized areas. The amount of funds now brought to a man on a teaching staff is insignificant compared with older times. It was a system of polite blackmail at the best. The threat was "If you don't come and teach our students and treat our patients, you shall not have a private practice." Such as it was, the method of those days led to thriving private practices, and to some extent it still persists among men who have passed through those days. It is the brilliant younger teachers who are feeling the effects of the surgical decentralization, and however great a reputation they may make by original research and technical ability combined, they cannot hope to attract surgical patients from the decentralized areas.

What will be the natural consequence of all this if the old system persists? In order to live the teaching class (without private means) will be compelled to become the surgeons of the decentralized areas where private practice awaits. If the best men are thus rendered incapable of teaching, what will become of the high standard of teaching that will be necessary for the subsequent supply of absolutely efficient surgeons? There will be a disastrous shortage of efficient teachers. The demand for great teachers can be met only by giving them high salaries. The public, having once grasped this problem, must itself see how it can be solved. It can be solved only by the action of Parliament and a Ministry of Health unhampered by political fetters.

ROYAL MEDICAL BENEVOLENT FUND

At the last meeting of the Committee seventy-one cases were considered and £658 was voted to fifty-four applicants. The following is a summary of some of the new cases relieved.

L.R.C.P.E.D. 1838 aged 73 met with a motor bicycle accident while acting as assistant and broke both legs and the right clavicle. At the suggestion of a member of the medical staff of the hospital the Fund with a view to getting him away to a convalescent home had made an emergency grant of £10 and a further sum of £6 was voted.

M.R.C.S. Eng. aged 80 whose investments have failed is with his wife and young daughter aged 47 now living on money received by the sale of household goods. This case has been investigated through the Guild and the report states that the old home in which they live by a mortgage on it for £750. The interest on this and rents amount to £57 a year. The eldest daughter aged 51 is a widow and is maintained by her son. An emergency grant of £5 was sent and the Committee voted £40 in twelve monthly instalments.

Widow aged 68 of M.R.C.P.I. 1830 who died in 1898. She is a trained nurse and has supported her self since her husband's death. She has just had an operation for cataract and has no means and is not well old enough for the old age pension. £5 was sent as an emergency grant and a further £15 was voted.

L.S. 1384 aged 62 who prior to the war was a ship surgeon, served during the war and until 1923 when he was demobilized. He has since made a small income as a locum tenens. In February last was ill and unable to get further employment. In November 1924 the Officers Association gave £5 to enable him to take a post and again in September 1925 a further £5 was given to his sister for his benefit. He has recently been a patient in King's College Hospital and the Fund was asked to help to get him to a convalescent home. £2 12s 6d was voted for this object.

M.D. Brux and L.R.C.P.E.D. 1897 aged 57 unable to get locum tenencies, has applied to the Fund for assistance. During the last twelve months has received £105 from locum tenencies and has had unfortunately to apply to the guardians to live who made an allowance for applicant and wife of 30s a week from September 11th. The rent of one room is £2 6d a week. The local secretary sends a satisfactory report. On his recommendation £5 was sent at once.

Widow aged 85 of M.R.C.S. Eng. who died in 1894. She is permitted to live with her daughter who is a housekeeper earning £50 a year. The applicant has the old age pension and an allowance of £4 from her eldest son. Three other married sons unable to help. The applicant pays 5s a week towards her board. Voted £30 in twelve monthly instalments.

Subscriptions may be sent to the Honorary Treasurer, Sir Charles Symonds, K.B.E., M.S., at 11, Chandos Street, Cavendish Square, London, W.1.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and suits for ladies and gals holding secretarial posts, and suits for working boys. Gifts should be sent to the Secretary of the Guild, 58, Great Marlborough Street, W.1.

British Medical Journal.

SATURDAY, NOVEMBER 21st, 1925

PHOTOSYNTHESIS AND THE ORIGIN OF VITAMINS

The progress of science as a whole is largely dependent on the mutual help afforded by its different branches, and it would be easy to multiply examples of the cases where new hypotheses of the greatest importance have been introduced to a science by a worker in another field. The suggestions put forward recently by Professor E. C. C. Baly, who holds the chair of chemistry in the University of Liverpool, regarding the possible origin and nature of vitamins, therefore deserve the careful consideration of physiologists.

Professor Baly, in summarizing his views on photosynthesis, begins by affirming that every chemical reaction consists of three separate stages: (1) the activation of the reactant molecules by the supply of a definite and specific increment of energy, (2) the reaction proper, whereby new molecules are produced in an activated condition, and (3) the loss of energy by the resultant molecules, which causes them to settle down into their normal and non-reactive state. Professor Baly points out that the second stage is the only one which is expressed by the ordinary equation of the reaction. He considers that this new theory of chemical change at once leads to the view that all chemical reactions may be divided into two main classes—namely, those reactions for which only a small increment of energy is necessary to activate the molecules, and those reactions for which a very large increment is required. Since the everyday methods available in the laboratory are capable of supplying only small quantities of energy, the whole of our experience of chemical reactions, he says, is necessarily restricted to the first class of chemical reactions.

High energy reactions can, however, be produced by the influence of ultra violet light, and Professor Baly has studied the reactions produced when ultra violet light acts upon mixtures of carbon dioxide with water, ammonia, and nitrates. He finds that under the influence of ultra violet light carbonic acid is converted into formaldehyde, and that this activated formaldehyde polymerizes to form hexoses according to the following equation:

These equations appear to represent the first stages in the photosynthesis of carbohydrates by living plants. The activated formaldehyde also can react with ammonium salts to form pyridine, which may represent the first stage of the synthesis of alkaloids by plants. Finally, the activated formaldehyde can react with nitrates to form nitrogenous bases and amino acids and these may represent the first stages of the synthesis of proteins by plants. The synthesis of every individual biochemical substance—carbohydrate, protein, and alkaloid—from the simple inorganic materials carbon dioxide and water, nitrates, and ammonium salts, remained a mystery so long as our experience was restricted to the laboratory processes, which are all of low energy. So soon as the field of high energy chemistry is entered, and study of the series of reactions initiated by the activation of

carbonic acid with an abnormally large increment of energy supplied by light is begun, the mystery begins to disappear. Each and all of the reactions peculiar to the living plant are then found to be quite normal and straightforward—as any reaction in the normal chemistry of the laboratory.

These conclusions are of the greatest interest in themselves, for they provide an explanation of the fundamental reactions upon which all life depends. Professor Baly, however, has carried his idea of the importance of high energy products in living matter a stage further, and has suggested that phenomena peculiar to living organisms may largely depend upon these containing activated compounds, and that the vitality of any organism, apart from all question of photosynthesis, depends on light. Finally, he has reached the following important conclusion: that although the theory leads to the view that the value of all foodstuffs is largely dependent on their energy content, yet modern biochemical research has established the existence of two or three substances of especial value, to which no name of vitamins has been given. I venture no opinion as to whether this restriction will be maintained by further research, for it has no essential bearing on my argument, but the conclusion seems to be forced upon us that these vitamins are compounds in a state of high energy content, and that their remarkable properties are due to this fact and to this fact alone. By this I mean that a vitamin is not a specific chemical substance which is thereby differentiated from all other compounds associated with it, but that it is one of these compounds in a high state of chemical activation.

This is, of course, a radically new view of the nature of vitamins, and it deserves most careful consideration, since it receives direct support from the recent experiments which have shown that the anti-rachitic factor appears when various substances, including cholesterol, are exposed to ultra violet light. The simplest test of the hypothesis would appear to be to ascertain whether light is essential for the production of vitamin B, and some workers also state that yeast can produce small quantities of vitamin A, but the presence of light is not essential for its growth. Again, germinating seeds produce large quantities of vitamin C, and here also the presence of light is not essential. Therefore vitamins B and C can be produced without the action of light, and there is some evidence that vitamin A also can be produced in the dark. There are various other objections that will have to be met before the attractive hypothesis of Professor Baly can be accepted in its entirety. Whatever may prove ultimately to be the truth, the new hypothesis will at any rate stimulate fresh lines of inquiry, and this, after all, is the most important function of any new hypothesis.

POTT'S DISEASE

It is within the memory of many now living that the connexion between consumption and what was called strumous caries of bone was firmly established, but more than three centuries have passed since Dr. Jacques Dalechamps, a Norman who had settled in Lyons, described the symptoms and complications of tuberculosis of the spinal column, which has since become widely known under the name of its second founder—if we may borrow a term familiar to

historians of ancient benefactions—Percival Pott. It is to be hoped that a much shorter time than another three hundred years will see the disappearance from this country of humpbacks due to tuberculous disease in children and adolescents.

In the discussion of this subject in the Orthopaedics Section at the Bath meeting (of which a report appears at page 937) more than one speaker commented on the diminution in the number of cases of severe deformity from this cause, due probably to early recognition and treatment of the disease, as well as to improved methods of preventing and correcting deformity. The excellent results achieved by means of open air treatment, reinforced as found necessary by ultra violet light, physiological rest, and conservative surgery, were well demonstrated by the two openers of the discussion, Sir Henry Gauvain and Mr. G. R. Girdlestone, the first dealt largely with methods of correction of deformity, while the latter largely emphasized the importance of permitting the formation of an angle at the actual site of disease as a part of the cure. In this, as in so much else in orthopaedic surgery, discretion and prudence are needed to point out to the surgeon how far he may safely go.

The means set forth by Sir Henry Gauvain and others as most useful in the correction of deformity require for their safe and successful employment highly trained and experienced nurses, with a degree of skill and experience in the use of special appliances which can only be obtained and kept up in special hospitals, or at least in special wards. Not the least important of the objects sought by the Central Committee for the Care of Cripples is the provision of a sufficient number of such highly trained orthopaedic nurses throughout the country.

Since the days of Hilton there has been a general agreement that rest is the primary need in the treatment of tuberculous joint disease, and fixation of the spine has been often spoken of, but, as Dr. Osgood of Boston reminded the Section, absolute and complete immobilization, in the thoracic region at least, is impossible without too great restriction of the normal movements of respiration. The bone grafting methods of Albee and others aim at completely fixing a part of the spine extending beyond the site of disease, but a majority of speakers considered that these operations should seldom be performed in children, except as a protective means in the later stages. Some surgeons in the past—let us hope that we are wiser now—have been too apt to treat the spinal column and the skeleton in general from an architect's or carpenter's point of view, and to forget that at the ages at which most cases of Pott's disease are treated they are living, growing structures. Hence came the failure of certain methods of correction now abandoned, and similar causes may prejudice the remote results in some cases which are now exhibited as triumphant successes for methods of correction. The humpback of an old case of spinal tuberculosis affecting the thoracic region is the outcome of two main causes. The one is destruction of bone in the front part of the column, which is not compensated by the formation of new bone, and the consequent ultimate falling together of the remains of the vertebral bodies. This produces the primary kyphosis which most surgeons now regard as inevitable. The other is the cessation of growth in the anterior segment of the spine only, its posterior segment, and also the ribs and sternum and the contents of the thorax, continuing their growth, in the course of which some exaggeration of the normal bowing forward of the sternum and ribs is bound to

occur, together with a corresponding backward projection of the dorsal portion of the spine. Time will show whether the production of small compensatory curves above and below the site of the disease, which produces a straightening of the column as a whole, may not have, if carried too far, a bad effect in restricting the capacity of the chest, and, by throwing the centre of gravity forward, in making the maintenance of equilibrium difficult.

Bearing in mind the grave differences in the course of the disease in adults as compared with children, there was a practical consensus of opinion as to principles among all the speakers on such important points as bone grafting, correction of deformity, and the treatment of abscesses and sinuses. On this last point Mr. Girdlestone quoted some most significant and impressive statistics showing the deadly results of septic sinuses and the overwhelming importance of aspiration as opposed to opening and drainage, unless the primary focus is accessible to treatment. The importance of a radiological study of the whole spine for the detection of multiple foci and other often unsuspected complications, which Mr. Turbank and Dr. Osgood emphasized, should be borne in mind in early diagnosis and treatment.

Once again the importance of the part played by milk in the causation of disease was stressed by Sir Henry Gauvain's quotation of some interesting statistics of the kind of bacilli found in the cases at Alton, which showed a great preponderance, in disease of the spine, of those of bovine origin, which appear to have a selective affinity for the joints and bones of the vertebral column.

THE LEAD TREATMENT OF CANCER

THIRTY years ago Professor W. Blau Bell of Liverpool claimed to have achieved remarkable results in the treatment of advanced cases of cancer by the administration of lead preparations. The treatment was based on certain theories he had entertained as to the nature of malignant disease. Since then three papers have been published by him, the latest of these, the subject of a lecture to the Toronto Academy of Medicine which excited great interest in the lay press, has appeared in the *Lancet* of November 14th. He believes that "malignant neoplasia is a specific growth process in that it is a reversion on the part of the striving cell to the nutrient seeking proclivities of its ancestral type, the chorionic epithelium," and that "a comparison between the chemical constitution of different tissues in regard to the factors concerned in growth processes demonstrates clearly not only that malignant tumours are richer in this respect than the corresponding normal structures and innocent neoplasms of the same parts, but also that the physiologically malignant chorionic villi show even higher values than pathologically cancerous tissues. The chorionic epithelium is super-malignant." The evidence so far put forward in support of any of the propositions is, however, neither sufficient nor convincing.

We have on several occasions during the last few years given some account of the investigations in progress at Liverpool into the effect of lead upon cancerous tissues, and Dr. J. G. Adams, F.R.S., in response to our request, has written us an interesting letter (printed at page 978 this week) in which he outlines the story of these researches.

The researches have been conducted by a staff working under Professor Blau Bell's direction and

(to quote his words) "in three years about 50 private interim reports have been circulated by members of the staff to their colleagues." It is possible that in these reports much of the information on which an outsider could form a judgement is contained, but so far as we are aware they have not reached other members of the scientific world. For example, it might be easier to appraise the value of the statement on which so much is built, that malignant tissues contain lecithin and other lipins in larger quantities than do normal somatic tissues. The information hitherto given on that point is inadequate. Again, the supposition that lead salts have a greater affinity for lecithin than for any other cell constituent would require more considerable proof than has yet been adduced. And so with all the other subsidiary contentions the evidence produced is small and the conclusions disproportionately great. To call normal epithelium super malignant seems to strain language.

But, whatever may be thought about the theoretic considerations, practical interest will centre round the efficacy or otherwise of the lead treatment. A question that at once arises is, Were these lead preparations extensively tested on tumours in animals before being tried in human beings? It is understood that Professor Blair Bell administers lead in some colloidal form. That the treatment has to be carefully conducted, and that the dangers are formidable, is made plain, but we have not seen any published account of the exact mode of preparation of these lead colloids, nor, so far as we are aware, has the mode of their preparation been made known to scientific inquirers beyond the circle of Professor Bell's immediate colleagues.

Further reports are promised in the near future. Without the additional information they may be expected to contain we must suspend judgement, and for this attitude of reserve support may be found in the later part of Dr Adams's communication.

DR H H DALE

THE announcement briefly made last week that a member of the profession and a research worker in medical science had been recommended for election as one of the secretaries of the Royal Society will have been received with particular satisfaction by all our readers. It is the practice of the Royal Society to have two general secretaries—the one distinguished in the physical sciences, the other in the biological. Dr Henry Hallott Dale, CBE, MA, MD, FRCP, FRS, upon whom this honour has fallen, comes, like so many others of our most eminent men of science, from Trinity College, Cambridge, where he obtained a first class in the Natural Sciences Tripos in 1897. He completed his medical education at St Bartholomew's Hospital, and after graduating in medicine in 1903 devoted himself to research. He first held the George Henry Lewes studentship, and then went to University College, London, as Sharpey scholar. He left University College in 1906 to become director of the Wellcome Physiological Research Laboratories, a post which he held for some eight years. During its tenure he made a number of discoveries of great importance to medical science. In collaboration with Brugger and Ludwig he worked out the active principles of ergot, and showed that in addition to the alkaloid ergotamine the drug contained the two putrefactive amines tyramine and histamine. The study of histamine led to the discovery of the action of the drug on the capillaries, and this knowledge is the basis of our present conception of the phenomenon of surgical shock.

Another outstanding piece of work was the analysis of the mode of production of anaphylactic shock, and the proof that the anaphylactic state was essentially due to an abnormal condition of the plasma muscle cells. In 1914 he was elected FRS, and the Medical Research Council appointed him to the staff of the National Medical Research Institute at Hampstead, where he is head of the biochemical and pharmacological department. In recent years a series of important researches have been carried out in this institute under his direction. We may recall in particular that workers at the institute have invented or perfected methods of biological standardization of a number of important drugs, including pituitary extract and insulin. Work of this nature is not so sensational as the discovery of new remedies, but the practical value of new and potent therapeutic agents depends on the accuracy with which they can be standardized. Dr Dale has received many other official recognitions of the high esteem in which his ability, his achievements, and his character are held. He has been, for example, Croonian Lecturer of the Royal Society (1919), Hexter Lecturer of Johns Hopkins University, Baltimore (1919) and Oliver Sharpey Lecturer of the Royal College of Physicians of London (1923). We may take the opportunity of recalling that he has in many ways shown his readiness to give assistance to the British Medical Association. He is an active member of the Science Committee, and has been for several years one of its visitors to report on the work of the Association's research scholars and grantees. The Science Committee, at its meeting last week, congratulated Dr Dale on the conspicuous honour now conferred on him by the Royal Society, and accepted with regret his resignation of the office of visitor. We are glad to add that he remains a member of the Committee.

USEFUL PLANTS OF INDIA

SIR DAVID PRIN, FRS, formerly director of the Royal Botanic Gardens, Kew, and of the Botanical Survey of India, was the lecturer at an evening meeting of the Pharmaceutical Society of Great Britain on November 10th. He dealt in the main with the two plants *cannabis* and *cinchona*. *Cannabis*, from the standpoint of the botanist, had to be dealt with as a plant of very distinctive character, of interest to commerce and industry as a source of a valuable fibre and of a useful oil, and of importance to pharmacy and medicine as a source of a potent but curiously unreliable drug. In spite of the nominal separation of the plant when grown as a narcotic from the plant when grown for its fibre or its fruit, and notwithstanding the subdivision into strains on which the fibre producer found it convenient to insist, it was not possible to disentangle the history of its economic and its pharmaceutical usages. Though wild in India it was not a native there, nor was it native in other countries where it had been met in a wild state. It was one of those plants of waysides and waste places which accompanied man in his migrations. After reviewing the history of the plant, and distinguishing known facts from hypothetical conjectures as to the origin and extension of man's acquaintance with its qualities, the lecturer dealt with the question of the variation in potency of the product prepared by pharmacy for use in medicine from raw material yielded by the hemp plant when cultivated as an excisable crop. The differences between *bang*, *ganja*, and *charas* were explained, the various kinds of *ganja*, in which pharmacy was more particularly interested, were discriminated, the nature of the changes known to take place in *ganja* was described, the possibility that the uncertainty of which pharmacy had to complain might be connected with these changes was suggested, as was also a method by which the

difficultly experienced in pharmacy and medicine might be overcome. As contrasted with cannabism, cinchona involved, from the hot medical standpoint, the study of a considerable number of closely allied but nevertheless distinct species, all of them natives of various parts of the Andes, from Colombia southward to Bolivia. Only a few of these botanically distinct species were of importance to medicine and pharmacy because of the value of their bark and its contents as remedies for malaria. If in this case the history of the discovery of the qualities of the crude drug was as obscure as in that of cannabism, the history of the exploitation in succession of crown, red, grey, yellow, and the Carthagena barks was easy to decipher as a whole from the record of isolated facts available. So, too, was the history of the circumstances that led to the substitution of the cultivation of cinchona outside South America for the exploitation of cinchona within that continent. The conditions that controlled the initiation of this planting enterprise were described, and the effects upon the conduct of that enterprise of medical preference and manufacturing policy were explained. The natural genesis of what had been abused as a monopoly, and the real character of what had been complained of as a shortage of quinine, were indicated. It was further suggested that perhaps the most suitable remedy for a somewhat unsatisfactory state of affairs might be found in a sustained effort to apply the results of recent medical research. It might be found that, after all, pharmacy, by holding fast to the belief that red bark alone should be regarded as official, had been at least in fully justified as medicine was in thinking that quinine was the cinchona alkaloid on which alone reliance could be placed, that cinchona barks other than yellow might once more be grown with profit, and that the bark of *remijia* might once more come into use as an auxiliary to that of cinchona.

THE SCHOOL MEDICAL SERVICE

In another page we begin a review of the Annual Report for 1924 of the Chief Medical Officer of the Board of Education. The work of the school medical service is now an integral part of the health services of the country. Although this service is of comparatively recent origin, it has been completely established in the regard of all parties concerned by its thoroughly practical character and because its work is of high value. Of the improvement which has been attained through it there can be no question. The children are healthier, and therefore the better able to take full advantage of the education provided for them by the community. If anyone should have a doubt about this, a reference to a single point will suffice to convince even the most sceptical. Let him refer to the statements regarding cleanliness. Twenty years ago a dirty head was very common amongst the girls, especially of the older years, a clean head was, in fact, a rarity. Now in London, in a great city where the vastness of the communal life affords every facility for the transference of vermin, there has been attained a high record of cleanliness even under the strictest of standards. The attainment of cleanliness is a worthy aim, one well worth securing even at some cost, for without it there cannot be comfort, and without comfort there can be no proper education. Besides the direct and indisputable gain to the children themselves, there is an added and wider advantage. The care that is taken of the children in the schools is impressed upon the parents, so that they learn to regard a high standard of health as of value, in this way the work of education is spread widely through the community. A work such as this, so directly beneficial to the race, so wide-reaching in its effects, must claim the interest of every medical practitioner, and there is ample evidence that it does, and in an ever-increasing ratio. The study of the review will enhance this interest.

REST-PAUSES IN INDUSTRIAL REPETITION WORK

DURING the last three years the Industrial Fatigue Research Board has paid special attention to the effects of breaking up long spells of repetition work of a high kind by the introduction of a rest—usually of ten minutes' duration—in the middle of a spell. A year ago the Board published a report (No 25) by Vernon and Bedford which showed that in several factories where the system had been tried it resulted in an increase of output amounting to from 5 to 10 per cent, in spite of the diminution of working time. The observations were made on large groups of workers and extended over several months, during which it was not possible to maintain uniformity in all the working conditions, such as temperature, ventilation, and lighting, the Board decided, therefore, to continue the investigation by an intensive study on smaller numbers of workers for shorter periods. In a report just published (No 32) Mr S. W. Watt, assisted by Mr J. A. Fraser, describe their observations on three small groups of workers for periods of three weeks before and after the introduction of a rest pause. They measured the rate of production over quarter- or half-hour intervals, and noted all the causes of delay, whether voluntary or involuntary. Thereby they obtained a clear picture of the activities of the workers investigated, before and after the introduction of the pause. In each instance there was an increase in the rate of working, the improvement varying from 15 to 8 per cent, and even after allowing for the productive time lost in taking the rests the total output showed an increase of 2 per cent in two instances, though there was a minute loss (0.7 per cent) in the third instance. Hence the favourable influence of the rest pauses was not so great as that observed by Vernon and Bedford, and thus for a very good reason. The workers usually take a considerable time to get thoroughly adapted to a change of conditions, and the full effect of introducing a rest pause does not show itself for three to six months. During this time the workers, feeling more vigorous and cheerful as the result of the rests, unconsciously get into the habit of working at a somewhat accelerated speed, and of taking somewhat shorter voluntary rests from their work. The writers of the present report draw attention to the fact that the operatives were numerous in their appreciation of the rests, and often volunteered such remarks as "The work is not so depressing," and "I feel less tired at the end of the work." Several other interesting points were established in the course of the observations. For instance, it was found that the group of girls engaged in folding handkerchiefs showed fairly large fluctuations in their rate of work at the beginning of the spell, but the fluctuations underwent a gradual reduction during the first two hours, and then, as fatigue and boredom became more pronounced, they rapidly increased again till they were at a maximum at the end of the work spell. After the introduction of the rest pause the fluctuations were smaller than before, and did not show a rapid rise till the last half-hour of the work spell. Again, it was found that the operatives who worked in close proximity influenced one another's activities to a marked extent. The rates of output of the handkerchief folders who worked nearest to one another showed closely parallel fluctuations, and for these and other reasons the conclusion was arrived at that it is important to include a few specially dependable and efficient operatives in any compact group of workers, in order that, by means of emulation, suggestion, and imitation, the more indifferent workers may be induced to maintain a higher standard of efficiency. The sceptic might maintain that the indifferent workers would be equally likely to infect the efficient workers. Fortunately this conjecture does not appear to be borne out in actual practice.

VICTOR HORSLEY MEMORIAL LECTURE

MR WILFRED TROTTER, M.S., F.R.C.S., senior surgeon to University College Hospital, has accepted an invitation to deliver the second Victor Horsley Memorial Lecture next July. The first lecture was given by Sir Edward Sharpey-Schafar in October, 1923, it was on the relations of surgery and physiology, and was published in our columns at the time (1923, vol. ii, p. 739). At a recent meeting of the trustees of the fund, with Sir John Bland Sutton in the chair, when the invitation was made to Mr Trotter, it was also decided to ask the Council of the Association to allow the lecture to be given in its house. This seems very appropriate when Sir Victor Horsley's services to the Association are recalled. He was the first Chairman of the Representative Body, which he had done so much to bring into existence, was a member of the Council, and in many other ways devoted much time and interest to its affairs. In the obituary notice published last week some account was given of the large share Mr Domville had in establishing the fund, to which he acted as one of the honorary secretaries from the beginning. The trustees had regretfully to accept his resignation, on grounds of ill health, at their meeting, and appointed Dr Alfred Cox, Medical Secretary of the Association, to be his successor. Mr Domville's motive in suggesting the establishment of such a fund was that it should commemorate the services of Sir Victor Horsley to science and the empire. The committee received subscriptions from all parts of the world, and a sum of over £1,000 was collected. This sum it was decided to invest in the name of trustees, who would triennially appoint a person to deliver the memorial lecture in London. The date suggested for the lecture next July is Friday, July 9th. Mr Trotter was for many years a colleague of Sir Victor Horsley at University College Hospital.

THE PATHOGENY OF MALARIAL COMPLICATIONS

HAEMOGLOBINURIA and jaundice as concomitants of malarial attacks are familiar to all tropical practitioners, but haematuria and purpura are much less frequently seen. Dr Trabaud has recorded in the *Revue de Médecine* three cases in which collectively all these signs appeared, and he offers an explanation of their pathogeny. The first patient had haemoglobinuria followed by haematuria, with renal colic and secondary pyelonephritis, but no jaundice, the second, jaundice and haematuria with marked uraemia, the third, jaundice and purpura, with a 20 per cent reduction only in red cells. The generally accepted explanation of the symptoms is due to haemoglobinuria from destruction of red corpuscles, attempts on the part of the liver to deal with this, and the excess passing on to be excreted by the kidneys, may be modified to show connecting links between the three recorded cases with their different symptoms. In the first, owing to the rapid liberation of the haemoglobin, efforts of excretion by the kidneys led to acute renal congestion and the passage of blood. In the second, the course of the disease being prolonged for three months, blood destruction was great but less rapid, and jaundice as usual followed. The haematuria Dr Trabaud explains as due to the setting free of haemolysis from the phagocytosis of the destroyed erythrocytes by the cells of the spleen and the vascular endothelium. This haemolysis might act as a toxin on the capillaries, renal or cutaneous. If the former, haematuria would result, if the latter, purpura. He postulates a case in which the whole of the symptoms could arise in the same patient. Thus, a massive corpuscular destruction might give almost immediate haemoglobinuria, as in the first case, prompt treatment (by serum injection, for example)

might avert the consequent haematuria, and by slowing down the blood destruction permit the intervention of the liver with the production of haemorrhagic jaundice, the resultant hepatic insufficiency might then manifest itself by a toxic action on the capillaries of the kidney, leading to secondary haematuria (as in Case 2) and of the skin, with the appearance of purpura (as in Case 3). The explanation is certainly ingenious, but more experimental work will be needed before the hypothesis is converted into fact.

CONTROL OF THE FOOD SUPPLY

WITHIN recent years the press has discovered that anything sensational about food will be read with avidity, and the public nowadays gets a great deal of information about food poisoning, microbes in milk, preservatives in pears, and so on. Since items of news that excite alarm or disgust are more acceptable than quieter records to those who read the papers for amusement, it follows that the former gain larger headlines and much more prominence than the latter. The publicity devoted to certain defects of the national food supply has probably given the ordinary reader a wrong impression of food hygiene in general because he hears, as a rule, only one side of the question. But though the scales of justice have not been held with steady hands, the cause of hygiene has benefited from the highly seasoned paragraphs on which the newspaper public is fed. This was brought out by Dr W. J. Howarth, medical officer of health for the City of London, in his recent Chadwell Lectures on the "Control of the food supply," when he acknowledged the debt of the public health official to journalistic presentation of food problems. Thereby the public has been prepared for the more stringent regulations about food promised by the Ministry of Health, and the work of medical officers of health and other officials has been received with something akin to sympathy. In his two lectures Dr Howarth gave a general review of the present state of affairs with regard to the control of food supplies in this country, and expressed the view that the position generally can be regarded as reasonably satisfactory, though there is room for improvement in certain directions. Within the last forty years great changes in food supply and distribution have been witnessed, and no doubt the better health of the masses should, at least in part, be attributed to these reforms. He laid special stress on two factors which have contributed to improvement—namely, the greater amount of imported food which now reaches this country, and the extension of the multiple supply system of shops and restaurants. Increased importation has led to increased supplies, this has brought prices down and allowed even the poorest family to vary its daily diet. The spread of the multiple shop system has resulted in a marked falling off in the sale of sophisticated foods. Large businesses with many branch establishments depend for their prosperity on maintaining a good name in all the districts they serve, and not one of the branches can be successfully challenged as being in default without this reflecting on every one of the company's other interests. Big firms buy in large bulk, engage expert buyers, and retain skilled chemists. They act as central distributors to retail shops which are maintained under the same central control. Dr Howarth described several instances in which the control of food supplies might advantageously be made more strict. We select one particular passage in his lectures because it deals with a question of pressing importance. He argued that present methods of controlling pasteurized milk are unsatisfactory, since only persons who are licensed may use the official term "pasteurized milk," but this regulation does not deter unlicensed persons from treating milk by some form of pasteurizing process and selling it in bottles under some fancy name such as

¹ *Revue de Médecine*, 1925, No. 6, p. 470.

"heat treated" milk, or by any other designation so long as the official plan is avoided. A considerable amount of milk in London to day is more or less efficiently pasteurized, though sold under unambiguous titles, but no standard of cleanliness is guaranteed, neither is there a guarantee that the milk has not been heated several times. Such heated milk is often sold as "fresh milk," a misrepresentation not easy to detect. The regulations should be altered, and it should be made an offence to treat any milk by heat without declaration on sale, and if to sold compliance with the requirements as to satisfactory pasteurization should be made compulsory.

BRITISH INSTITUTE OF RADIOLOGY

IN the account given of the Congress of Radiology in London at the beginning of last July mention was made of its international aspect (July 11th, p. 75), a matter which was emphasized also by several speakers. A practical step was taken when Dr. Robert Knox, chairman of the executive of the British Institute of Radiology, made a suggestion at the concluding meeting of the international delegates that some form of international club should be established, and extended an invitation to any member of a recognized foreign radiological society who might visit London in the future to make use of the facilities of the institute in Welbeck Street without financial obligation. He expressed the hope that some similar arrangement would be made in each country throughout the world. The purchase of the lease and the essential furnishings of the institute building have absorbed the available capital from the Mackenzie Davidson memorial fund and from private donations. Part of a bank mortgage remains to be cleared, and donations of money, books, and diagrams will be welcomed. The Congress proceedings are being published in the *British Journal of Radiology*, preliminary reports appeared in August and September, and in the October number are included the papers read by Dr. C. Regaud of the Paris Radium Institute, Professor A. Bayet of Belgium, Dr. H. H. Herg of Frankfurt-on-Main, Sir Frank Colver, and Dr. T. W. Pearson of Baltimore. The complete set of special Congress issues of the *British Journal of Radiology* may be obtained from the secretary of the institute at 32, Welbeck Street, W.1, price two guineas.

THE REGISTRAR GENERAL'S "STATISTICAL REVIEW"

WE announced a few months ago (August 8th, p. 277, and August 15th, p. 301) that the Minister of Health had issued a circular to public health authorities, boards of guardians, and Insurance Committees, stating that the Registrar General was in a position to make a special offer of the two parts, "medical" and "text," of his annual *Statistical Review* at the price of 12s. 6d. a year instead of £1, on condition that the subscription would be continued for five years. Mr. Vivian informs us that although the response has not reached the expectation formed, the degree of success realized has been such as to enable him to obtain the Treasury consent to the continuation of the arrangement. Subscribers will accordingly be furnished with copies of the volumes for 1924 and future years within the subscription term at the reduced price. Mr. Vivian asks us to state that it will not be possible to keep the subscription list open indefinitely, and that the higher price will be charged to all purchasers who do not enrol themselves as subscribers before the list is closed. Early application to him at the General Register Office, Somerset House, W.C.2, by all those who, not having already subscribed, desire to obtain the benefit of the reduced price, is therefore advisable. In the circular issued by the Minister of Health it was pointed out to public health authorities that they may legitimately cut of their funds

provide the volume for their medical officers, and the same principle will apply to other classes. In commenting on the proposal we observed that we believed it would not fail to command hearty approval, adding that no municipal library, and no library of any institution or organization relating to health and disease, could be complete without having the reports on its shelves. Every committee and every official dealing with any section of health administration ought to have immediately available the volumes both of tables and text. They will be found rich in suggestion as to many problems affecting preventive work. The principle of supplying the volumes to subscribers at a reduced price appears to be sound. We hope the response will be so general that it may be possible to reduce the subscription price still further at the end of the quinquennium.

INTERNATIONAL TREATMENT OF SEAMEN SUFFERING FROM VENEREAL DISEASE

THE Minister of Health announces (Circular 634) that an international agreement relating to the treatment of venereal diseases amongst seamen has recently been ratified by His Majesty on behalf of Great Britain and Northern Ireland. Under this the contracting parties undertake that facilities shall be available, at each of their chief sea and river ports, for the gratuitous treatment of merchant seamen, without distinction of nationality, and such facilities are to include out-patient treatment, in-patient treatment when the medical officer of the treatment centre considers it to be necessary, and sufficient medical supplies to carry out necessary treatment during the voyage to the next port of call. The agreement also requires that each patient shall be supplied with a card for providing a brief record of the diagnosis of his case, the treatment given, and the treatment to be followed during the voyage. Apart from the provision of medical supplies for treatment during the voyage to the next port of call, the necessary arrangements are already in force in this country, and the Minister will be prepared to approve the supply to a seaman patient for his treatment during the voyage to the next port of call of such drugs, dressings, and appliances as the medical officer of the treatment centre considers necessary, and as, in his opinion, can safely be used by the patient himself. A list of treatment centres in the chief ports throughout the world, prepared by the British Social Hygiene Council, is enclosed with the Ministry's circular.

ROYAL MEDICAL BENEVOLENT FUND'S CHRISTMAS GIFT

IT has been the practice of the Royal Medical Benevolent Fund for many years to present to the annuitants and some of the most necessitous grantees a Christmas gift of 25s. The treasurer of the fund now makes an appeal for £350 to keep up this practice. Last year the remainder of the Dinner Fund raised in 1913 was used for the purpose, but this reserve has been exhausted, and though subscriptions are coming in satisfactorily the committee has not in hand the amount necessary to make, this coming Christmas, the gift to which the recipients in former years are no doubt looking forward. It is a generous and friendly act, and we have no doubt that many readers will wish to make its continuance possible. Subscriptions may be sent to the treasurer, Sir Clunton Symonds, K.B.E., M.S., at the office of the fund, 11, Chandos Street, London, W.1.

THE twelfth Memorial Huxley Lecture will be delivered by Sir Oliver Lodge, F.R.S., on Thursday, December 3rd, at 3 p.m. in the out-patients' hall of Charing Cross Hospital. The subject is "Recent advances in science in their relation to practical medicine," and medical men will be admitted without tickets.

CUMBERLAND INFIRMARY PAST, PRESENT,
AND FUTUREBY
NORMAN MACLAREN, M.A., M.B., B.Ch. Cantab.,
F.R.C.S. Eng.
Surgeon to Cumberland Infirmary

In 1828 Carlisle was a very different city from what it is to-day. At that time only a few years had passed since a broad turreted wall had enclosed the city. On the south stood the castle with its frowning battlements, and on the north the city, named in accordance with the direction to which they pointed—the English, the Scottish, and the Irish—were shut at sunset. Armed sentinels kept watch and ward over them as if still threatened by the Scottish foe. The military parade gave life and colouring to the otherwise passive character of the city, the demizens of which were roused from their slumbers by the call of the bugle horn, and after the labours of the day were reminded of the hours of repose by the evening tattoo. To the traveller approaching from the south what a pleasant picture of a city, when the sun shone fair on Carlisle, and that wall had no other environs than the meadowed plain, the converging mountain streams and the knolled and wooded eminences beyond. The mail coach still plied through Carlisle, taking four days from Edinburgh to London, God willing. Ten years were still to pass before the first railway line from Newcastle entered the city. For only the past nine years had transport by water been effected by the ship canal to Port Carlisle, memories of which still remain near us in 'Port Road' and the 'Joiner Sailer Inn'. With increasing population the character of the city was becoming changed. Devoid of archaeological thought as well as architectural taste, persons guided only by the hope of pecuniary advantages had begun to erect wretched buildings in close proximity to the gates, and thus marred not only the beauty of the border city, but its well known natural salubrity. It was indeed fortunate that at this time there were in Carlisle two medical men Dr Heysham and Dr Thomas Barnes, to whose foresight and wide public spirited outlook the inception of the Cumberland Infirmary is due. Dr Heysham, the author of the *Carlisle Tables of Mortality*, had lived in the city since 1778 and had paved the way by forming and working at the Carlisle Dispensary since 1810. He had also materially helped in the work at the fever hospital or house of recovery since it was established in 1820 in a house on the outskirts of the city long since demolished to make way for the present station. Dr Thomas Barnes, who had come to Carlisle in 1817, took a very active part in establishing the Cumberland Infirmary and many of the early facts in connexion with its foundation are gleaned from a small book entitled *The Founding of Infirmarys*, which he published in 1830 to further this worthy cause.

It may not be irrelevant to take a general view of the medical establishments already provided for the sick poor of Cumberland and Westmorland. In 1830 Carlisle had a dispensary and fever house. About 3,000 patients were annually registered in the dispensary. The fever hospital was confined to patients with infectious fevers—mainly typhus fever, about 60 patients

were admitted annually. At Whitehaven there was also a dispensary and fever house, nearly 3,000 patients were annually admitted to the benefits of the former charity. The fever hospital was open only for the reception of persons affected with infectious fevers during 1829 nineteen persons were admitted. The subscribers to the Whitehaven dispensary had for many years a small fund which they hoped would one day assist them in establishing an infirmary.

The proceedings at Carlisle gave impulse to their generosity and compassion. Soon after the public meeting which will shortly be mentioned a meeting of the subscribers to the Whitehaven dispensary was held at Whitehaven and it was resolved to set afoot a subscription for the establishment of a hospital. A house and garden in Howgill Street were purchased, and the premises were converted into an infirmary, fever house, and dispensary.

At Kendal there were a dispensary and lying in charity from which between one and two thousand patients annually received medical and surgical aid. Between 1828 and 1830 a house of recovery for the reception of persons affected with infectious fevers was also established at Kendal. Cockermouth had a dispensary which was conducted on an economical plan and was productive of much good. The surgeons of the town attended the poor gratis, and supplied them with medicines,

the expense of which was defrayed by subscription. Between 1828 and 1830 a dispensary had been established at Workington and fully proved its utility to the indigent sick of that town and neighbourhood.

It had long been the custom in various parts of Cumberland to send patients who required institutional treatment to the Edinburgh New castle, and Dumfries infirmaries and it was very evident that a public infirmary was much needed, not only for the necessitous sick poor in Carlisle, but also for those of whom this object in view.

Cumberland and Westmorland. With this object in view a meeting of a few friends and promoters of the establishment of a general infirmary in the county of Cumberland was held at Carlisle on November 27th 1828 with Mr John Hodgson, the mayor, in the chair. The following resolutions were unanimously adopted.

- 1 That it is in the opinion of this meeting that an infirmary for the reception and relief of the sick poor would be highly beneficial to the county of Cumberland.
- 2 That convinced of the advantages that would result from a county infirmary the gentlemen present deem it eminently entitled to their patronage and support and will use their best endeavours to promote its establishment.
- 3 That as the late Thomas Parker Esq. of Warwick Hall has bequeathed the sum of £1,000 towards carrying the above object into effect and as Anthony Longlake Esq. has offered to give the sum of £500 and the Ladies Committee of the Carlisle Bazaar have signified their intention of giving the residue of their Fund amounting to £380 for the same purpose the present appears to be a fit and proper time for setting on foot this work of charity.
- 4 That a provisional committee be appointed to carry forward this business.

A public meeting was held at the Carlisle Town Hall on August 24th 1829 and it was unanimously resolved that a public infirmary should be established and that a committee should be appointed to obtain money to choose a site and plans for building and formulate regulations. At a general meeting held at Wigton on January 18th, 1830, it was resolved that the land situate near Caldcoates Carlisle, which had been approved by the committee should be purchased, and that the

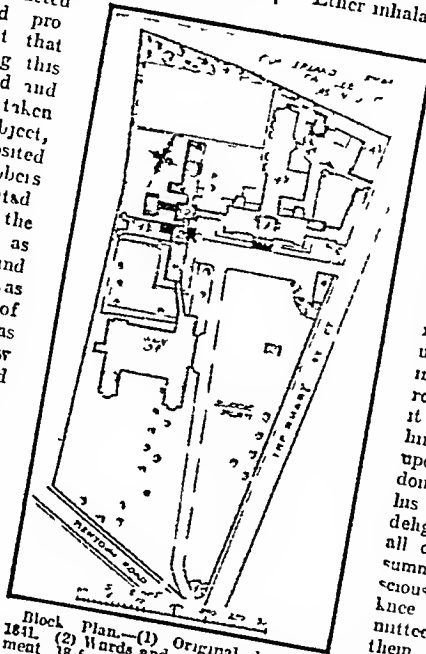

From an old print showing the original building 1841

CUMBERLAND INFIRMARY

Earl of Lonsdale the Lord Bishop of Carlisle, Sir J P G Graham, Bt, the Rev Sir C J Musgrave Bt, and Sir Wilfrid Lawson be appointed trustees to the institution

The plan submitted by Mr Tattersall of Manchester was considered the best and was adopted at a general meeting held at Carlisle on May 15th, 1830. The foundation stone of the infirmary was laid on October 1st 1830. In especial Provincial Grand Lodge of Masons was held for the purpose by Sir J R G Graham, Bt, M P, Provincial Grand Master of Cumberland and the Dean of Carlisle and the clergy, and the mayor and aldermen. The Bishop delivered in appropriate prayer, a vase containing coins, pavers etc was deposited in a niche of the stone and over it is placed a leaden tablet bearing an inscription. Sir J R G Graham then laid the stone according to the ancient forms of Masonry, and afterwards addressed the assembly. The record states that this interesting and solemn spectacle excited deep and general interest. An immense multitude of all classes were assembled and conducted themselves with great order and propriety. It is a matter of regret that during the Thursday night following this ceremony the foundation was removed and the urn containing the coins, etc, taken away. Plunder, no doubt was the object, but the whole of the coins deposited must have been woefully disappointed. Great force would be required to raise the stone and to separate it from the rest, as four tonnes of very large size were bound together with iron clamps. The stone was relaid by the workmen in the presence of the writer of the record, Dr Thomas Barnes on November 18th, 1830. A few coins and papers were first deposited, and the plate which had been left at the building was replaced. During the excavation in 1908 the foundations of the north east corner of the old house were found to be covered with a large amount of cement, evidently placed there to prevent further puffering but the plate was not seen.

Block Plan.—(1) Original building (2) Wards and out patient department 18.6 (3) Operating theatre and nursing home 18.5 (4) Ward 1908 (5) New out patient department in course of construction.

The building was 134 feet long, and was divided into five compartments. In the centre was a tetrastyle portico of the Doric order, and in imitation of the Choric monument of Thrasyllus and Thrasyvelles in the street of Athens. The portico with its Pausanias, under the south side of the bold extended flight of steps in front led to the entrance to the infirmary. The principal and end fronts were built with white freestone from Chalk Quarry, rubbed and polished. Chalk is considered the handsomest and most durable stone in the neighbourhood of Carlisle. The building was so contrived that it might be enlarged later at a moderate expense without lessening its architectural uniformity, the end fronts of the first erection being made to form one wing of the future flank elevation.

The early days of the charity were not all plain sailing through want of funds and misunderstandings with the contractors and it was not until 1841 that the edifice of the Cumberland Infirmary was complete and it became necessary to appoint the staff. An able physician was readily found in the person of Dr Thomas Barnes but owing to difficulties with local medical practitioners an influential deputation communicated with Mr Scott of the London Hospital with a view to the selection of a competent surgeon for the institution and on his recommendation Mr William Bousfield Page was appointed.

Describe his first journey to Carlisle Mr Page graphically records the hardships which had to be encountered when travelling by the mail coach. He narrates: "Forty three years have passed since almost frozen I arrived from London at the Bush Hotel in this city on a mid winter afternoon having travelled in a biting frost outside the coach from Preston. All sensation in my lower limbs was gone by the

time I had got over Chap I tell and when I had taken off my boots I had to look to see whether my feet were still in them.

His first visit to the hospital he describes as follows: "I bring to mind my first visit to the hospital an old man and woman occupying the kitchen and other rooms every room except the first patient came on the second day after my arrival—a course provided with instruments of my own and having secured the service of a Miss Gamp and with the able and ever-ready assistance of Dr Barnes and the help of an apprentice of the drugists of the town, I operated with double flaps in the middle of the thigh. In less than a fortnight the limb was firm and entirely healed. The case was simple and satisfactory except in one particular. There were no the days of anaesthesia and no small difficulty was experienced in completing the operation from the violent struggling of the boy and the inefficiency of our power to control him during its performance."

Ether inhalation was used at the Cumberland Infirmary within a few days of its being first employed in England for anaesthetic purposes. Mr Page records.

It so happened that a patient of mine was consulting Mr Liston in London and at the end of a letter to me respecting the patient he told me how he had just operated on a person rendered insensible to pain by ether and he described roughly the manner in which it was employed. When I went to the infirmary the house-surgeon and I went to work and having improvised a gum-bottle sponge and tube with the ordinary medicinal ether we got the pupil to allow us to experiment upon him. He was seated in an armchair from which he very soon rose like a man uproariously drunk, and it was only by the house surgeon tumbling him over on to the floor and then lying upon him that he was able to prevent his doing mischief to himself or to others until his consciousness returned and we were then delighted to find that he knew nothing at all of what had happened. Dr Barnes was summoned and while she was quite unconscious a young woman was cupped over the knee and Dr Barnes hastened to the Committee which was sitting as he wanted them to come and see the then wonderful sight.

While examining the early annual reports of the hospital I have come across one other fact of interest, especially in these days of internal secretions—namely, that Thomas Addison, F.R.S., of Guy's Hospital, was an annual subscriber to the hospital of one guinea for the last sixteen years of his life—from 1844 to 1860. He was a friend of Dr Goodfellow, Dr Lonsdale, and Mr Robert Brown—all members of the staff in those times. Throughout his life he retained a very warm regard for his family home at the Banks near Lanercost. One likes to think that during his visits to the North he may have found time to accompany his friends round the Cumberland Infirmary and discuss with them the problems of the diseases of the lungs on which he did so much, and possibly may have seen a case of anaemia with pigmentation, which helped him to correlate the symptoms of the disease with which his name will ever be associated. He now rests in the churchyard of the Lanercost Abbey while inside the church is a marble slab with an inscription to his memory. I may here record that Guy's Hospital has as a result of a letter in the BRITISH MEDICAL JOURNAL (February 9th, 1924, p 250), undertaken to provide for the upkeep of his altar tomb in perpetuity.

For thirty years the work of the hospital was carried on in the original building but by the end of the sixties it was evident that further accommodation was urgently needed. Two factors were no doubt predominant in producing this want—namely (1) that Carlisle was becoming a large railway centre with the necessary increase of population, both temporary and permanent (2) the publishing by Lister of his articles on antiseptic surgery in the *Lancet* of 1867, which caused a new

era to arise in the surgical world Carlisle may, I think, rightly claim some credit in helping the "master mind" in elucidating the principles which revolutionized surgery and have made his name immortal. I quote from Dr Wiensch—*Lord Lister, his Life and Work*.

The Carlisle authorities had for many years made use of carbolic acid to abolish the odour of sewage. Lister heard of its success, and went to Carlisle to see the process for himself. Lister concluded that it prevented the odour by killing the cause of putrefaction—namely the microbes. Other surgeons also knew of this power of carbolic acid to decrease faecal matter and they had used it in offensive wounds for that purpose. But they had not understood the mode of its action; they used it unintelligently and consequently with very varying and sometimes harmful results. Lister used it intelligently. He used it before the faecal matter arose; he used it deliberately to kill the causes of the condition that gave rise to the faecal matter.

In the Cumberland Infirmary matters were no better or no worse than in the other hospitals of the kingdom. Mr Herbert Page, who knew the hospital in those days, writing to me early this spring, says:

As to the surgery in the Cumberland Infirmary before Listerian days the less now said the better. With its small wards it was a hot bed of unceasing pyaemia, and it was no wonder that P. M. Bradwood, one of the house surgeons, should have gained the Astley Cooper Prize of the Royal College of Surgeons of England for 'Pyaemia' in 1863.

Ultimately with the sanction of the governors a wing containing accommodation for seventy-two beds in four large wards was built on the west side of the old hospital, and also a block on the east side containing the dispensary, waiting rooms, and consulting rooms for outpatients. These were formally opened in September, 1877. With the completion of this extension the hospital afforded accommodation for one hundred patients, at the same time there were corresponding changes and increases in the staff—medical, surgical, nursing, and domestic.

Further evidence of change of view of disease at this date is shown in the encouragement of fresh air and sunshine in treatment, by the establishment of the Cumberland and West morland convalescent home at Silloth in 1862.

Miss Enderby, who still lives at Clifton (Bristol), was appointed matron of the infirmary in 1883 and made many good changes, and Miss Allen in 1888 further improved matters by enlarging the staff of probationers to twelve, thus starting the training school for nurses. In 1894 the accommodation for nurses was increased by additions above the out-patient department, and a private nursing branch was instituted, which continued for many years. When the staff was augmented in 1896 arrangements were made for regular lectures and examinations. Of structural alterations the most important took place in 1899, when the operating room, which is still in daily use, was built and equipped at a cost of £2,000. The laundry, mortuary, and post mortem room were built in separate blocks.

It was during these years that the pioneer work which followed on Lister's revolution of surgery was faithfully and zealously carried out, and we of the present day owe much to the skill and initiative of those whose lot it was to carry the art of surgery and medicine into then untrodden paths.

In 1908 a new kitchen and nurses' wing—named the Barnes Wing, after the late Dr Henry Barnes—were built, also additional ward accommodation in the King Edward VII Memorial Wing, containing a male medical ward of thirteen beds, and on the first floor a children's ward to accommodate twenty-four cots. The heating and water supply (hot and cold) of the hospital was reorganized and the steam laundry erected near the boiler house. It is indeed fortunate that these additions were complete before the war, for they without doubt greatly facilitated the carrying out of the increased work of the hospital in those trying days, when it provided treatment for 669 wounded soldiers, 559 munition workers, and 84 discharged and disabled soldiers. When the railway accident occurred at Gretna on May 22nd, 1915, 180 cases were treated, 78 remaining as inpatients.

The Present

The central block, or "Old House," remains much as the architect left it in 1841, with its four imposing columns and steps at the central entrance. The wards have all been removed

from this portion of the building, and only the ward name boards over the doors remain to remind one of the early benefactors of the hospital—Parker, Bishop Percu, Rulton, Huddleston, Atwick, Lamb, Chambers, and de Whelpdale. The cellar and ground floor are now given over to stores, rooms and administration, secretary's office, and residents' quarters. The first floor temporarily accommodates the x-ray and electrotherapeutic and venereal departments until the new out-patient department is built.

The present out-patient department and dispensary, which have been in constant use since 1876, are situated on the east of the central block, connected with it by a corridor. They will shortly be vacated for the new out-patient department now in course of construction, and it is intended to remodel this portion for the venereal department. The wards are placed to the west of the main block, and consist of two stores served by a centrally placed electric lift for taking stretcher cases. On the ground floor are the male wards (George Moore and Page), north and south of the connecting corridor, each containing eighteen beds, with one side ward and the additional annexes. In addition there is the male medical ward (King Edward Ward) of thirteen beds, built in 1908. On the upper storey are corresponding female wards (Dean Close and Princess Louise), with the children's ward of eighteen cots in the King Edward block.

The operating theatre, opened in 1899, is connected with the ground floor by a corridor opening behind the lift.

The nurses' home—"the Barnes Wing"—built in 1909, is situated behind the centre of the "Old House," and is approached by a glass covered conservatory on the first floor. There is bedroom accommodation for forty-eight nurses, with dining hall, sitting room, and lecture and reading rooms on the ground floor. Between the "Old House" and the nurses' home on the ground floor is placed the kitchen, which has service both to the hospital and the nurses' dining room. The domestic staff are housed above the present out-patient department.

The present number of authorized beds in the hospital is 111, with six extra beds on balconies during the summer months.

The Future

In 1919 the governors sanctioned a scheme for the further extension of the hospital and appealed for funds, £30,000 was raised, including a grant of £1,200 from the Joint War Committee of the British Red Cross Society and the Order of St. John of Jerusalem in England.

Eight proposals were included in the programme of extension: (1) new out-patient department, (2) pathological laboratory, (3) electric lift, (4) new operating theatre, (5) isolation accommodation, (6) renovation of "Old House," (7) additional ward accommodation to increase the hospital to 160 beds, (8) additional accommodation for doctors, nurses, and servants. The increased cost of building delayed the proposed work, but in 1924 the lift was installed at the west end of the hospital and the plans of the new out-patient department were adopted. Building operations in the grounds south of the hospital were commenced in the spring of this year.

When this building is complete, which I hope will be during my year of office, the whole of the out-patient departments with the exception of the venereal, which is going into the old out-patient rooms, will be housed in one block connected to the main building by a corridor under Page Ward. This arrangement, it is expected, will materially facilitate the administration, as the various units of the hospital will then radiate from the main staircase and lift. The remaining six proposed extensions are very necessary to equip the hospital efficiently for the work that it is being called upon to undertake, and it is only the question of ways and means that prevents them being put in hand at once.

The thirty-fifth Congress of the French Association of Surgery will be held at Paris, under the presidency of M. J. L. Faurc in October, 1926, when the following subjects will be discussed: Pathology of the semilunar cartilages, introduced by MM. Mouchet of Paris and Trucner of Lyons; Conservative operations on inflammatory lesions of the kidney, introduced by MM. Tuffier of Paris and Chauvannaz of Bordeaux; Treatment of active gonococcal arthritis, introduced by MM. Mondor of Paris and Michel of Nancy.

FIRST INTERNATIONAL MALARIA CONGRESS

The First International Malaria Congress was held in the Exhibition Palace at Rome from October 2nd to 6th last.

The delegates representing various Governments and societies were officially welcomed by Senator Cicerone, in the name of the King of Italy, and the Congress was formally opened by His Excellency Benito Mussolini, the Prime Minister, on October 4th.

At the first meeting the French delegate, Dr. A. Michaux of Paris, presided at the lecture given in place to Colonel Jancz, the director of the Institute of Hygiene.

The following day the Italian delegate, Dr. G. Bignard, presented a paper on the treatment of malaria.

NAME on some of the pathologic changes occurring in
malaria, the latter differing from the former in regard
ing these is degenerative and proliferative, never of an
inflammatory nature.
Professor Victor Schilling (Germany) brought forward
evidence that the blood picture in malaria is by no means
so definite as the textbooks would lead us to believe, but
that, in other diseases, there is a "leucocytic curve," i.e.,
changes with in uncharacterized prodromal phase, a reaction
phase of combat phase of diminution of defense or
phases (mononucleosis), and a phase of healing, (as in
phlebotomy and lymphocytosis). In malaria the changes are
healed, rapid and tended to overlap.

Epidemiology
Group of

[illegible]

Amongst other papers communicated to this section was one by Professor Lachme Sargent, which led to fruitful discussion, it was concerned with the importance of having at command several methods of control which might be called for in combination, such as treatment of a prophylactic administration of quinine, education of the family, and so on. Dr. Kähler dealt with the question of the affected Pile time in particular. Professors Nocht, Schuller, Mühlen, Seidenreich, Brumpt, Colonel Jané, and Dr. Bentley were among those who took part in the subsequent discussion.

In the section devoted to Statistics Dr. Abtner dealt with malaria in the

Statistik

Statistics

In the section devoted to propaganda and statistics Dr Abtineer dealt with the prevalence and effects of malaria in the French colonies, and J. S. or Khin, with malaria in Sweden, showing that that country is an example of "anophelism without malaria," though in his opinion zoophilism alone did not afford an adequate explanation. Dr Ahmed Nihney Bey of the Public Health Department, Cairo, presented a report on the work of the Egyptian Malaria Survey for the last nine years, giving the results of the measures adopted. A communication in which the conditions, is, regards malaria in the Soviet Republic, received by Professor Nuznoski, and a paper on malarial prophylaxis in the Suez Canal zone, by Dr P.

The section devoted to malaria in the Soviet Republic, received by Professor Nuznoski, and a paper on malarial prophylaxis in the Suez Canal zone, by Dr P.

Department

The section dealing with the all kinds of encephalitis and
infectious therapy was marked by a general interesting com-
munication, starting with a general survey of the former
and their etiologic preparation, by Dr Kaufmann of
Switzerland and followed by a paper by Dr Dicks and
Colonel Jaffe jointly on the relative therapeutic effects of
quinine, quinine, and encephalitis, in which they showed
that the curative effects were the same for all forms of
infectious, and that, except for the relative cardiac degree
of action of the two, there was no difference in toxicity
on the two papers, together with one by Profe or Asch
on the personal experience with one of the specific treatment
of malaria, were discussed by Professors Griesa, Schaffner,
Mullens, Peroni, and others.

Pathology

Pathology
A paper by Prof. or Neuf (Cagliari) on complement in malaria was of more scientific than general interest. He quoted Rubezky's observation that there was a marked fall serum of complement during a malarial attack and stated that the same held good in chronic malaria. He suggested that this might explain cases of active malaria without clinical relapses. Papers were contributed by Prof. or Dürk of Munich and Prof. or Bürginn of

The Parasites
one by the

The first paper was one by the President on the unity or plurality of the parasites of malaria. The record changes in types of parasites and the fact that in the blood of I was found when it was relapse occurred after their return home, the large amoeboid forms predominated or, perhaps, were the only ones found. On the other hand, it was demonstrated that differences between examples of the same type (such as *P. falciparum*, and *P. malarie*) were equally marked. Further, the different times of evolution, though practically constant for each species, the invulnerable in mission of the same type to highly susceptible subjects, therapy is evidenced by the effect of arsenical preparation to support the idea of pluridity. Professors Mahlenz (Hamburg), Casio (Rome), Brumpt (Paris), Pitt lugn (Madrid), and Swellingel (Amsterdam) took part in the discussion, all favoring pluridity, while the last named, having found pluridity by experiment, suggested the use of these for a final diagnostic method in cases where blood examination failed either to find or determine the nature of the infection. Dr. Sidiac Buen (Spain) read a paper in support of the pluridity theory on epidemiological grounds.

The Parasites

A second subject which brought up the question of diagnosis is that designated "Therapeutic Use of Malaria." Professor Auerbach (Vienna) presented a paper in support of the therapeutic use of malaria in various diseases. He discussed the value of malaria in the treatment of certain nervous diseases, particularly in the case of hysteria and neurasthenia. He also mentioned its use in the treatment of certain forms of epilepsy and in the management of certain types of insanity. The paper was well received and led to a lively discussion.

Therapeutic Use of Malaria in Psychiatry

Therapeutic Use of Malaria in Psychiatry

A second subject which brought up many interesting points was that designated malarial fever. In this section Professor Augusto Minio presented a paper on malaria therapy in psychiatry, in which he pointed out the importance of blood controls, discussed the use of quinine and its uses of general paralysis recovered such a degree of stabilization as enabled them once again to resume family life and social responsibilities. He uttered a warning, however, against too great optimism in regarding these anchored patients as cured and not merely remissions.

The possible treatment of malaria as a mordant for specific medication mentioned, and a proposal put forward for it employment in other cases of cerebro-spinal syphilis and in non-psychic mental disease such as dementia praecox, confusion of mind, and lethargic encephalitis. Colonel Juncos and also Professor Mahkens pointed out the risks of the desferal molarion method especially about the dangers substitution might be moved with the dangerous substance tetra- (though Profes or Gharum of Rome were both) partly on this account, and partly because relatively of patients objected, perhaps mainly to direct inoculation employ infected mophics, the results, more or less apparent to be more satisfactory than when the direct blood inoculation method was used.

A paper by Profes on Neuropathology indicated a view of more recent researches of the same kind.

The section on malarial fever concluded.

... ..

Concluding Session

The final session of the Congress dealt first with the work of the Malaria Commission of the League of Nations, briefly detailed by Dr. Luzzatto, as Chairman of the Commission. This was followed by Professor Pittaluga, who discoursed on the factors of variability of endemic malaria in Europe, mentioning in particular the transfer of the virus by movements of population, and its corollary the transfer of people into an endemic area, the modification in domestic life and land cultivation in relation to man and animals, and insufficient quinine.

The concluding paper, by Professor Nocht, on new researches on the pathogenesis of blackwater fever, is of great interest at the present time in connexion with British work in Rhodesia. He showed that by injecting dogs with haemolytic serum and the same serum in combination with quinine it is the amoebocytes alone which bring about haemolysis, but that if haemolysins are present their effect is greatly stimulated by quinine. Thus, as Professor Nocht observed, does not, of course, prove that blackwater fever is produced in the same way, but it certainly indicates a line of research worth following up.

Among the motions unanimously adopted at the termination of the Congress was one brought forward at the instigation of Dr. Fernando Perez, the Argentine Minister in Italy, recommending the creation in Rome of an International Malarialogical Institute.

THE HEALTH OF THE SCHOOL CHILD

In the Annual Report¹ for 1924 of Sir George Newman, the Chief Medical Officer of the Board of Education, are correlated the reports of the medical officers of a great number of local education authorities, and a number of observations and suggestions are added, pointing out possible lines of advance.

The school medical service is a great piece of team work. Parents, teachers, attendance officers, care committees, nurses, and the school medical officers all combine together to ensure the success of the work, and there is everywhere evidence that they are really working together. Prejudice has gone, respect for and readiness to co-operate with the work is now established. Last year every education authority in the country fulfilled its statutory obligations with regard to the medical inspection of the children committed to its care, 2,420,305 children were inspected, most of these were at routine inspection in the three age groups: entrants, children 8 years of age, and children 12 years of age. Special examinations desired by teachers or parents were made in 722,744 cases. Since there are over five million children in the schools, that means that half of them were examined during the year.

Personnel

To do this work there are 1,844 medical officers, of whom 821 are whole-time, the remainder being private practitioners. The total does not include many who do work for the schools indirectly through arrangements with hospitals, as, for instance, in school clinics. Besides these there are 511 dentists. The figures include 289 women doctors and dentists. The nurses number 4,869. The work of the nurses is very valuable. Their immediate contact with the children in their homes contributes largely to the popularity of the work of the school medical service with the parents. The work done by the many voluntary workers on the school care committees, the efficiency of the school attendance officers in discovering the causes of absences from school, and the increasing powers of observation of the teachers, cannot be put down in figures. It is sufficient to remember that without the work of these three groups the medical personnel would be well-nigh valueless.

Medical Inspection

The report has an added value over those of earlier years, for there has now come into use a revised edition of model tables for the use of the local education authorities in the

¹ The Health of the School Child. Annual Report of the Chief Medical Officer of the Board of Education for the year 1924. London: H.M. Stationery Office, 1925. (Pp. 189. Price 1s. 9d. net.)

presentation of the chief facts and findings in connexion with the inspection and treatment of the children in the schools, so that the national figures are comparable on a common basis. Of the children, 20.2 per cent in the three age groups were found on inspection to require treatment. Besides these many had defects which required them to be kept under observation. The table giving a classification of the main defects shows that there has not been an appreciable change since last year, save in two respects. There is an increase in the number of cases of "malnutrition," and in nose and throat diseases. The increase in the latter conditions is thought to be referable to the climatic character of the year, in the former there is some evidence that it is due to the general stiffening up of the standard of the normal. If there be any definite evidence of a decline it is in the nutrition of the very young children.

Personal Cleanliness

The revolution in cleanliness that has been accomplished can scarcely be realized except by those who took part in the earliest school inspections. When these began in 1902 in many schools scarcely a girl was free from infestation, and vermin could be seen dropping from the heads of the older girls as they stooped over their lessons. To-day the standard of cleanliness expected in London is very high and rigorous, for a single nit to be found in a girl's head removes her from the class of clean children. Even so, last year there was attained the highest record for cleanliness amongst the elder girls: 82.5 per cent passed.

Following Up

The value of following up cases of defect through the nurses and care committees is especially noteworthy, the results of the medical inspections lead to the conclusion that much subnormal health amongst the children is not wholly due to the presence of definite disease. It is more often due to unsuitability of diet, absence of personal hygiene, physical or mental strain, and lack of rest. For the correction of these disorders influence that can be brought into the home is essential.

Secondary Schools

The inspection of children in the secondary schools is becoming steadily more efficient. On the whole the average of good records is slightly higher amongst these children than amongst those in the elementary schools. But there is still to be seen the round-shouldered spectacled pupil with ungainly walk, the traditional student type, in too abundant numbers, in spite of modern ideas of physical culture, in both the higher schools and the colleges.

Nursery and Open-air Schools

The nursery school meets a need that exists in the greater cities, particularly in their congested districts, in the main these schools are conducted on open-air lines. Amongst these babies there is the discovery of much defect that would otherwise be missed, and possibly become established in some serious disability. So that in these districts the nursery school presents a double advantage—immediate and future.

Open-air schools for the children of ordinary school age are becoming more numerous. Local authorities and managers of schools are slowly awakening to the requirements of a somewhat extended class of listless, pale, anaemic, and debilitated children, of whom there are representatives in every school. Open-air education calls for no elaborate organization or equipment or undue disturbance of school routine. A playground affords sufficient chance, probably the only additional article of equipment required is an awning for protection when necessary. In London thirty-three classes have been formed in parks, open spaces, squares, or gardens, and sixty-two in playgrounds. Sir William Hamer reported:

Generally the beneficial results in the case of debilitated children were remarked upon. Children who previously suffered from frequent attacks of bronchitis have had no attacks since attending and children suffering from anaemia have improved, although the poor summer (1923) and lack of sun were unfortunately adverse to the best results being obtained. Most of the reports refer to the increase of mental alertness, improvement was also noted in carriage and physique.

Akin to these facilities are the organized school journeys and school camps which are growing in popularity. Some authorities have provided open air classrooms in their schools. A few modern schools entirely constructed on the open air principle have been established in Derbyshire, on the North Wingfield type, under the direction of Mr. George Widdows, the architect.

Juvenile Employment

The law strictly limits juvenile employment. No child under the age of 12 years may be employed for gain, but a child between the ages of 12 and 14 years may, on any day in which he is required to attend school, be employed after school hours till not later than 8 p.m. The children are examined as to their physical fitness for employment, and in many cases periodical medical inspections of these children are held. One school medical officer writes:

"Whereas formerly many children arrived at school fagged from their early morning employment, and incapable of giving attention to their lessons they are now fresh and alert. Indeed the experience of seeing a child fall asleep across the desk hitherto a frequent occurrence, is now but a memory of a decadent past. A suspicion of tiredness on the part of the child sets inquiries in motion and any improper employment is immediately stopped."

Cost of the Service

A tabular statement is given of the costs of the medical service under the heading of medical officers, nurses, travelling expenses, drugs and material, spectacles, contributions to hospitals, office expenditure, including clerical assistance. The last item accounts for about one eighth of the total expenditure. The gross total amounted to £1,220,268 in 1923-24, or about one fiftieth of the total cost of public elementary education—not a high premium to pay for health insurance.

(To be continued)

THE CARE OF MENTAL DEFECTIVES

ADDRESS BY DR. DEVINE

THE Berkshire Panel and Local Medical Committee held a public meeting at Reading on November 10th, when members of the county council, guardians, social workers, and others attended by invitation to hear an address by Dr. Henry Devine, O.B.E., F.R.C.P., of Portsmouth, on "The care of mental defectives." A representative company attended and listened with great interest, as they were all acquainted with the distressing results that spring from allowing mentally defective persons, even of high grade, to engage in the struggle for existence without special education and continued care and supervision. The motives of the committee in calling the meeting were indicated in a report printed in the SUPPLEMENT of November 7th (p. 166). The arrangements for the meeting were made by Dr. P. Napier Jones, and Dr. J. McCrea of Wargrave, the Chairman of the Panel Committee, presided.

Dr. Devine began his address by remarking that in all civilized communities the problem of mental disorder had now become the subject of serious consideration. The incidence of mental disorder was difficult to estimate, but the number of persons rendered less efficient by reason of mental weakness probably tended to increase rather than diminish. The notified insane in England and Wales numbered 131,551, and their cost to the community, excluding that of private patients, was £6,953,804 in 1924, besides these there were 19,376 mental defectives under care, and also an unknown number of inadequate personalities, alcoholics, and neurotics whose social efficiency was more or less impaired.

Regarding the particular problem of mental defectives, experience had fully confirmed the views of the Royal Commission appointed in 1904 to inquire into the whole subject. The Commission reported that there were numbers of mentally defective persons whose training was neglected, over whom insufficient control was exercised, and whose wayward and irresponsible lives led to much crime and

misery, much injury to themselves and others, and much continuous expenditure wasteful to the community and to individual families. In view of these findings it was clearly the duty of the community to provide school, institutions, and supervision for these badly endowed individuals whenever the family had not the means to provide for their care and treatment. In devising appropriate treatment it had to be borne in mind that they were incurable in the sense that it was obviously impossible to provide them with intellectual attributes denied them at nature, that they therefore needed institutional care, guardianship, supervision, or guidance, according to the nature of their defect and their circumstances, throughout their lives and, lastly, that education and training were just as necessary for them as for the normal person.

As an outcome of the Royal Commission's report the State had devised mechanisms in the shape of the Mental Deficiency and amended Education Acts of 1914, which made it possible for the local authorities to put these principles of care and treatment into operation. Unfortunately, however, the war and economic conditions since the war had prevented many authorities from making the necessary provision for these cases, with the result that the Board of Control in its report for 1924 stated:

"Urgent cases, to the number of many hundreds have been and are being discovered for whom no vacancies in existing institutions are available. The country has in this respect come for the time being at the end of its resources. Since the existing institutions are full unless the local authorities give immediate consideration to this matter the beneficent intention of the Mental Deficiency Act will be hampered and will almost cease to operate. We take this opportunity of making an appeal for immediate action, and we do so more confidently because every year reveals clearly the terrible consequences of the neglect to afford this means of protection. Lack of accommodation means degradation, crime, pauperism, and disease to individual defectives, and all the expense to the community which is invariably attendant on those conditions."

The whole position turned upon the efficiency with which the education authorities carried out their function in relation to the mentally defective person. It was only by discovering these cases when of school age that continuity of provision for treatment of defectives, which it was the aim of the law to supply, could be attained. As things stood, these defectives were first discovered in many instances when they came under notice owing to some delinquency. It was essential that special schools or classes should be organized for defectives. If they were taught haphazard with other children their restlessness, stupidity, naughtiness and inattention caused disorder in the class as a whole, and exhausted the energies of the teacher. The defective child itself could grasp nothing of what it was taught in an ordinary class, acquired a sense of inferiority, and naturally became bored, withdrawn, irritable, defiant, and apt to play truant. Teaching designed to interest these children should be arranged of such a kind that the manual rather than the intellectual functions were developed. In this way some defectives might be able to earn something for themselves when they left school, and in any event, whether placed in institutions or kept at home, they could be turned to some extent into useful social units.

In conclusion, Dr. Devine impressed upon his hearers that to deal effectively with the problem of the mental defective the co-operation of the whole community was necessary. Such co-operation must be organized, however, and he strongly recommended that a branch of the voluntary Association for Mental Welfare should be formed in the district. Experience at Portsmouth had shown that this association performed an invaluable function. It had the full support of the statutory committees, and its officials worked in the closest co-operation with the borough officials whose duties brought them into contact with the mental defective. It was difficult to see how the work which had already been done at Portsmouth could have been carried out without the assistance of that excellent organization.

At the close of the address a number of pertinent questions were asked by members of the audience and replied to by Dr Devine, and a vote of thanks to him for his address was proposed by Mr G F SLADE, MBE, JP, and carried by acclamation.

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER

THE Royal Commission on Lunacy and Mental Disorder resumed its public sittings on November 10th, under the chairmanship of Mr H P MACMILLAN, KC.

The Problem of Certification

SIR MAURICE CRAIG was the first witness, and was examined on the subject of certification. He said that certification was a legal matter, and yet a medical man was directed to carry it out, and thus became responsible in law for a medical statement which by statute became a legal instrument. Such a statement could be challenged by the person against whom it was made, and could be taken by him before a legal tribunal to which no medical assessors were attached. It was no matter for surprise that medical men in increasing numbers were refusing to sign certificates on the ground that they did not understand the meaning of legal insanity.

Mr Jowitt, KC, one of the commissioners, said that he was impressed by the fact that, rightly or wrongly, the medical profession was apprehensive and wanted protection. He wished to know specifically what protection was desired. Sir Maurice Craig replied that medical men, even if they had protection, were afraid of having their time taken up by defending actions at law, even though their defence was successful. What had brought about the present unrest was recent legal proceedings. Mr Jowitt asked whether the medical profession wanted protection for a dishonest or a careless certifier. The Chairman said it had been urged by some witnesses on the medical side that the certifier should enjoy an immunity similar to that of a witness in a court of law, who had absolute protection unless he perjured himself. Sir Maurice Craig said that personally he would prefer to have it in this way, that any court in which an action was heard or in which a certificate was challenged should have medical assessors, and that the decision should rest with the judge alone (apparently he meant, sitting without a jury). Mr Jowitt said that to make any lunacy system work satisfactorily, the goodwill of the medical profession had to be secured, and at the present moment he did not quite see what the profession wanted. Sir Maurice Craig said that what the profession wanted was to be kept clear entirely of the anxieties and troubles attending this purely legal function. Certification was a legal matter, and the legal people ought to take it over. The Chairman said that the Commission would be very sympathetic with regard to anything which would restore the confidence and comfort of the medical profession. Some device was wanted which would protect the profession, and yet would not give the public the idea that dishonesty was being protected. Even the legal members of the Commission were puzzled by this problem. Sir Humphry Rolleston asked whether it would not be advisable to create a specialist class of medical officers, analogous to tuberculosis officers, who would undertake this responsibility. Sir Maurice Craig thought that on the whole this might be advisable, an officer holding a public position might be considered by a section of the public more trustworthy than a private practitioner.

Treatment of Early Insanity

Sir Maurice Craig went on to say that experience had taught him that the harm done by certifying patients in the early stages of insanity far outweighed any advantages. If such certification were done away with the whole outlook of psychological medicine would be changed. Patients in the early stages would be more willing and co-operative, knowing that treatment would not endanger their liberty. Provision for the treatment of willing patients should be made in the general hospitals or in special hospitals or clinics, entirely apart from mental hospitals.

Passive or non-volitional patients, who did not express their wishes, should be granted the same freedom from certification, at any rate for such a reasonable time as would permit of their recovery if possible. With regard to unwilling patients, although from a medical standpoint it was unfortunate that they should be penalized as a result of their hostile attitude, nevertheless he appreciated the difficulty of enforced detention without some form of notification or certification. These must continue to be treated in mental hospitals under some legal restraint. He believed that all mental hospitals should be permitted to take voluntary patients, and that, until fresh accommodation was found, the non-volitional group of patients should be admissible to these institutions without certification. Patients belonging to the willing and to the non-volitional groups should be permitted to go to nursing homes or the houses of medical men. Experience had taught him the great value of small well-run homes and of single care. Many patients preferred to be treated in this way instead of in large hospitals. He appreciated that in non-volitional cases some form of notification would be necessary, but the most satisfactory method would be registration and inspection of all nursing homes as opposed to a routine inspection of the patients.

The Chairman said that where the present system seemed to fall short was in the provision of early treatment and in the accommodation of those cases of insanity which were not certifiable. Sir Maurice Craig instanced the difficulty in the case of the patient who had lucid intervals, who was sane at certain times and not at other. Was such a person properly described as sane or insane? Mr Michlem, KC, said that legally such a person would be considered as of unsound mind. The legal test propounded in the statute was objective rather than subjective. Certifiable insanity had relation to a person's conduct and behaviour and the extent to which he was a danger to himself or others. Sir Maurice Craig said that medical men would prefer to treat such persons as not insane. The Chairman remarked that it appeared to be a cardinal drawback of the present system that before the full benefit of medical treatment could be obtained a patient had to be pronouncedly insane. Sir Maurice Craig said that the position was comparable to holding up treatment in a case of phthisis until there were cavities in the lung. In reply to Mr Michlem, he said that certification, not detention, was the stigma. He thought that the clinics for early treatment should have some power of infringing liberty if necessary, but the safeguard to the public would be that such infringement was temporary and incidental to treatment, and therefore it would not create a stigma.

With regard to the central authority responsible for supervising patients in early stages, Sir Maurice Craig said that for many years he had felt that the Board of Control was too much steeped in the traditional treatment of mental disorders, and that it might in practice be difficult to have this body visiting patients who were not insane. But it had been impossible to watch the work of the Board during recent years without appreciating to what extent it had taken the modern view of psychological medicine, and he now thought that this body was fitted to undertake the supervision of all mental cases, including those in the early stages. But the medical side of the Board should be strengthened, because any ordinary visitation of the willing or non-volitional patients should be entirely medical. Out-patient clinics for those suffering from mental disorders should be available at all hospitals, and he was of opinion that the system existing at Guy's was the best, with one neurological department where all patients, whatever their nervous complaint, attended.

A representative of the National Society for Lunacy Reform was permitted to put a question to Sir Maurice Craig on a statement made by him (Sir Maurice) that some two-thirds of the medical students who qualified during the years 1921-24 were not required to show any knowledge whatever in their written papers on the subject of mental diseases. Sir Maurice Craig said that in spite of the overburdened state of the medical curriculum he must insist that psychiatry should have a larger share in it, because it touched on so many other branches of medical knowledge. He wanted to see it more fully dealt with as an ordinary subject in the curriculum, and also to have more provision for those who were making a specialist study of the subject.

Research in Psychiatry

Dr F L GOLLA, director of the pathological laboratory in the mental hospital department of the London County Council, gave evidence on the subject of existing facilities for research in psychiatry.

Dr Golla described the Maudsley laboratory, with its bio-chemical, bacteriological, psychological, and pathological departments, and said that this central laboratory had a consultative function in respect to the various mental hospitals of the county of London. Specimens requiring special investigation for which the hospital staff could not find time were sent there, medical officers from the various hospitals were encouraged to go there for consultation, and a number of them were seconded to Maudsley for an intensive course of three months' duration during which they learned the routine methods of investigation in the laboratory and studied the development of 'borderland' cases in the wards. He considered that the solution of the problem of research in psychiatry lay in the grouping of various mental hospitals around a central laboratory. In the provinces perhaps a group of counties might cooperate to support one research institution which would be available for all the mental hospitals in the area. The supervising authority, such as the Board of Control, should insist that medical officers were given adequate leave for study to perfect themselves in methods of investigation, and governing bodies should be educated to regard time spent in investigation as part of the essential duties of the officer.

Adolescent Mental Disorder

Dr A F TREDGOLD, Miss EVELYN FOX, and Miss FLORENCE ANDREW, representing the Central Association for Mental Welfare, gave evidence chiefly with regard to adolescent mental disorder, a condition which they said, was widely prevalent and fraught with grave menace to the general well-being. These were not cases of incipient insanity, and they could not be dealt with under any existing administrative procedure. The condition, nevertheless, was one which rendered the individual socially inefficient or antisocial, and necessitated supervision, training, and treatment which could not be given at home. The association urged that local authorities should be empowered to establish training homes for these young persons, that such homes should provide skilled and adequate treatment appropriate to mental disorder, as well as industrial and other forms of training, and that persons should be admitted to such homes on the application of parent or guardian, or, failing this, on the application of the local authority, accompanied by a medical certificate stating that the person was suffering from mental disorder not certifiable under either the Mental Deficiency or the Lunacy Acts.

Mr JOWITT doubted whether this matter came within the Commission's terms of reference, which excluded mental deficiency, and a long argument ensued as to whether the persons concerned were mental defectives within the meaning of the 1913 Act. Dr Tredgold said that these young persons had developed normally up to a point, but control had broken down, and therefore they did not come in as mental defectives, which supposed a congenital condition. The Chairman said that he recognized the difficulties of this intermediate class, but the category was so indefinite that he thought the less rigid bond of charity might meet the case rather than the setting up of another type of retarded home, which would mean a certain sacrifice of independence. In reply to a question by Sir Humphry Rolleston, Dr Tredgold said that the number of cases of mental disorder accompanied by misconduct arising from lethargy and other forms of encephalitis in recent years had accentuated this problem. Sir Humphry Rolleston thought there might be a case for an amended Mental Deficiency Act, and the Chairman remarked that it was a question whether the existing definitions of mental deficiency were not too rigid.

The witnesses also stated that machinery should be provided for the adequate investigation of all persons charged with offences against the law in whom there was reason to suspect the presence of mental disorder or abnormality.

The Commission afterwards held a meeting in private, and adjourned to a date to be announced.

Nova et Vetera.

THE VICISSITUDES OF A DICTIONARY OF MEDICINE

AFTER having been for upwards of thirty years an incommensurable work of reference, the *Dictionnaire de Médecine* edited by Littré and Robin, has become out of date, but the vicissitudes of its various editions, published during the later part of the last century, form an interesting chapter of medical history which has been related recently by Dr Maurice Geuty in the *Presse Médicale*.

It was in 1806 that it occurred to Brosson, who was a doctor as well as a publisher, to produce a dictionary of medical terms. He entrusted the task to one Joseph Capuron, an ex-seminarist and a popular obstetrician, but the work was so badly done that when the next edition was called for it was placed in the hands of Claude and Nysten. The third edition, which appeared in 1814, bore Nysten's name only, and when he died in 1818 the dictionary changed publishers, though Nysten's name still appeared on the title-page, and was still there in 1855, when J B Brillière entrusted the revision of the tenth edition to Littré and Charles Robin.

Littré, who was a member of the Académie des Inscriptions et Belles-Lettres, was already well known by various medical writings, by the earlier volumes of his translation of Hippocrates, and he was in many respects an ideal editor for such a work, but both he and Robin were fervent adherents of Auguste Comte's new religion. Robin was a doctor of sciences, had been professeur agrégé at the School of Medicine since 1847, and was the author of upwards of a hundred communications to the learned societies.

This new edition, the tenth, made its appearance in 1855. Littré took charge more particularly of the philological part, and he added a glossary in six languages, of which he rewrote the Greek-Latin section. To Robin was entrusted the articles on natural history and general anatomy, and working together they corrected etymological and grammatical errors, and, being unwilling to relinquish "all general ideas, all higher doctrines," they emphasized the principles of the Positivist philosophy. In this wise their dictionary became a channel for enunciating the new scientific methods to which they were devoted. The new edition was a success, and an eleventh was soon called for.

It was at this juncture that Nysten's widow—Nysten's name having been retained at Littré's express desire "in order not to efface all trace of our predecessors"—claiming that the philosophical views set forth in the volume were no longer those held by her husband, wrote to the authors requesting them to omit all mention of Nysten's name. Thereupon the editors, hoping to encounter the difficulty, adopted for the 1866 edition the following title: *Dictionnaire de Médecine d'après le plan de Nysten*, adding that the edition had been entirely rewritten by Messrs Littré and Robin. In this way the work retained the name of the original author to whom it had owed its first success. Madame Nysten, however, was not satisfied, she summoned the editors before the Tribunal of the Seine, laying claim to the property of the dictionary, she demanded substantial damages, and that her husband's name should be altogether suppressed. The verdict was against the miserable widow except in respect of the last matter. The matter was taken to the Court of Appeal, which, in February, 1866, ordered the editors to pay the widow pecuniary compensation "for the damage done to the memory of her husband" by publishing under his name certain philosophical and moral doctrines which had nothing in common with those he entertained.

These legal proceedings were followed by a political agitation of formidable dimensions. The facts that in 1866 Robin had for four years been a professor in the Paris School of Medicine, and had been elected to the Académie des Sciences, with the support of Princess Mathilde, Taine, and Sainte-Beuve, did not disarm those attacking him.

"Attacked," said Tunc, "because he brought philosophical views into his science." The Catholic party, which deeply disliked and resented the liberal tone of the lectures in the State faculties, more particularly in the Paris School of Medicine, set on foot a fierce campaign against Robin, and appealed to the Minister, who was fain to recognize the minority of the accusations against him. The next move of the clerical party was to present to the Senate a huge petition, directed not only against Robin, but against Broca also, who was accused of having referred to Malthus in apologetic terms. Vulpian and Charcot were also denounced for having laughed at a patient who was wearing a religious medal.

In the indictment drawn up against Robin the principal item was the part he had taken in the new edition of the *Dictionnaire de Médecine*, which, it was alleged, "corrupted the young." D'Est-Ange was instructed to draw up a report, it was presented on March 27th, 1868. After pointing out that the outcome of his inquiries was to show that circumstances allowed of a very different interpretation from that advanced in the complaint, he assumed the petitioners that the Minister had warned the professors that any non department that "might shock beliefs worthy of respect" by useless digressions would be promptly dealt with, and finally advised that no further steps should be taken.

A few days later, April 10th, 1868, being Good Friday, a dinner was given at Sainte Beuve's house to which Laine About, Renan, Flaubert, Prince Napoleon, and Robin were invited. The particular day was chosen by chance to suit one of the guests who was leaving Paris. It was not a "demonstration" or a "baquet," but Cardinal Donnet, one of the clerical leaders, and his friends accused the diners of eating sausages and black pudding on that holy day, and once again denounced Robin's obvious atheism.

The Senate debated the conclusions of d'Est-Ange's report on May 19th, 1868, and Cardinal Bonnechose formulated his recension against the *Dictionnaire de Médecine*. It was, he said, looked on at the School of Medicine as a student's manual. It was a short dictionary of medicine, a very convenient work, since any information required could be found in it. This dictionary, the cardinal continued, had been in existence for a great number of years, but had undergone a transformation. Its author was M. Capuron originally, and it was quite Christian and spiritual, so was the second edition, edited by M. Nysten, in its tendencies. Since M. Nysten, MM. Robin and Littré had prepared several new editions which were stamped with their materialistic doctrines. M. Robin was a follower of Auguste Comte, the lamentable founder of Positivism, and M. Littré shared these views. He then quoted from various articles, and wound up by proclaiming "the necessity for uniting science and religion."

Sainte-Beuve delivered a speech in which he took up the cause of Broca, Charcot, Vulpian, Avenfeld, Robin, and See, and claimed entire philosophical liberty for his views. "I have the honour," he remarked, "of having been a student in the Faculty of Medicine which is attacked in the person of its most illustrious teachers. To it I am indebted for the spirit of philosophy, the love of accuracy and of physiological reality, and whatever good method has passed into my writings."

The Minister, in a short speech, asserted that the recensions had no foundation in fact, but promised that "if Robin's teaching proved to be based on materialism he would be punished." The debate had occupied no fewer than three sittings. The result left the clerical party very angry, and the attack broke out afresh, but in a way that had no relation to the dictionary, which henceforth pursued the even tenor of its way. In a new edition the eighteenth, in 1878, the editors thought well to recall the history of the volume, and contended by reference to the texts which had been attacked in 1866 and 1868 that if anyone was open to the accusation of materialism it was rather Nysten than they. It would, no doubt, be possible to indict them for Positivism, but not for materialism; they claimed, indeed, that in their philosophy materialism, an absolute doctrine, was repudiated. Positivism was a relative doctrine.

Later on the dictionary appeared under Littré's name only, though Robin's signature was appended to certain articles, and phrases which might lend themselves to a philosophical controversy were altered or eliminated. Robin was greatly vexed, so he set to work on a *Nouveau Dictionnaire abrégé de Médecine* (published by Doyn), in which was to be found "the scientific and purely philosophical spirit of the original Nysten." He accomplished this gigantic task unaided in three years. The first part (480 pages) appeared in February, 1885, and at the date of his death the second part (519 pages) was in the press, it appeared on December 22nd, 1885. Dr. Littré corrected the last proofs, and M. Variot, with the assistance of the editor's notes, wrote the preface.

With the publication of the *Nouveau Dictionnaire abrégé de Médecine* the history of the Littré-Robin dictionary ended. It was one of the most remarkable medical works of the nineteenth century.

England and Wales.

COMPLIMENTARY DINNER TO SIR WILLIAM HODGSON

THE Cheshire Local Medical and Panel Committee recently arranged a complimentary dinner to Sir William Hodgson, chairman of the Cheshire County Council. The guests included Dr. H. G. Dain, chairman of the Insurance Acts Committee of the British Medical Association, the chairman of the Cheshire Education Committee and the coroners for East and West Cheshire, Dr. Mush, J.P., chairman of the Cheshire Panel Committee, and the county medical officer of health. A Latin inscription in praise of the approximately fifty years' service of Sir William Hodgson appeared on the menu cards, ingeniously designed by Dr. Pietou. The chairman, Dr. Mush, proposing the health of Sir William Hodgson, translated the inscription, and referred to the distinguished nature of their guest's services, which included the representation of Lancashire, Cheshire, and Westmorland on the Insurance Acts Committee of the British Medical Association. Sir William Hodgson, in his reply, expressed the hope that he would be able to continue his active fighting whenever it might be required. He had much enjoyed the work on some of the Panel Committees, and had found himself able to make many close friends in the course of the years he had spent in public life. One of the urgent necessities of the present time in connexion with the medical side of the Insurance Acts was the right of appeal to a court of law, without which there was always danger of triennial treatment. Taking the medical profession as a whole there was no better class than the panel doctor, and it was wrong to judge the whole by the few black sheep who were to be found among them in every profession. Dr. Dain, replying for the visitors, urged the importance of loyalty to the Insurance Acts Committee, without which there was danger of such harmful divergence of opinion as had been recently expressed in London.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION

A meeting of the London Association of the Medical Women's Federation was held on November 10th at the headquarters of the British Medical Association, Tavistock Square. The occasion was marked by the inauguration of the new president, Dr. Christine Marrell, and the delivery by her of the presidential address on the tendencies of the medical profession of to-day. She appeared rather pessimistic at the outset contrasting the position of respect and esteem held by the "family doctor" in the past with the rather anomalous position of the hosts of specialists and G.P.s of the present time. She emphasized the necessity for the training of men and women whose function it should be to exercise a not only on a certain scientific intimate knowledge of the patient and his surroundings—upon the various and often conflicting reports of the specialists. She deprecated the practice of the present time whereby the patient made his own diagnosis and

selected his specialist, often without reference to a general practitioner at all. She dealt also with the more obvious defects of medical education, stressing the fact that the newly qualified student, although well equipped to recognize and treat rare and urgent cases, had little or no knowledge of the commoner and slighter forms of disease. Dr Murrell's remarks were in the nature of a challenge to discussion, and a lively argument ensued, among the speakers being Mrs Flemming, Mrs Bunney, Dr Casson, Dr Tinsford, Dr Dobie, Miss Gordon Holmes.

CONVEYANCE OF MATERNITY CASES IN LONDON

Representations have been made to the London County Council by various bodies and persons to the effect that the night facilities for the conveyance of maternity cases to hospital should be extended to the whole twenty-four hours. During the night, when the ordinary means of transport are not available, the conveyance of women to maternity hospitals is undertaken by the Council's ambulance service, this can be done during the night hours without interference with the primary function of the service, the removal of casualties from the streets. The number of patients conveyed under this arrangement last year was 1,414. The ambulance service is also available, at any time of the day or night, on the application of a medical practitioner or registered midwife, for the conveyance of a maternity case in which sudden emergency arises and hospital treatment is desired, provided that the doctor or midwife accompanies the case, 661 such cases were dealt with by the ambulance in the daytime last year. It is estimated that to extend the night facilities to the day would mean an increase of about 20 per cent on the total number of calls received by the ambulance service, and would require the addition of four ambulances to the existing fleet. The authorities of the maternity hospitals have been asked by the Council whether the present methods by which parturient women reach hospitals in the daytime cause harm to the patients, and whether materially increased benefit to public health would result from the free conveyance of patients during the daytime, regard being had to all the circumstances. An unqualified reply in the negative to both questions has been received from thirteen hospitals and qualified replies from eleven, of which only three express themselves definitely in favour of the suggested extension. The Council therefore considers that no case has been made out for an extension of facilities.

Ireland.

A CRITICISM OF MODERN MEDICINE

DR V M SYNGE, F.R.C.P.I., president-elect of the Dublin University Biological Association, stated in the course of his inaugural address that the great age of Greece produced the greatest physician of all time. After Hippocrates medicine flourished for six hundred years, sank to insignificance and contempt amidst the superstitions of the Middle Ages, to rise again at the Renaissance. In the last eighty years medicine had progressed with increasing speed to its present proud position. Modern medicine could boast of a great increase in the average duration of life. Many infectious diseases had yielded to preventive measures. Plague, typhus, enteric—to mention only a few—had been practically banished from civilized communities. Preventive medicine had rendered life in the tropics comparatively safe for Europeans. Modern precautions had minimized the risks of industrial processes, and had maintained the health of the workers. Modern surgery had achieved wonderful cures of previously hopeless conditions. Great advances had been made in knowledge of the functions of the different organs of the body and of the causes of disease. Medical knowledge was very great, but everything was open to criticism, and modern medicine had its shortcomings as well as its glories. The incidence of all diseases was not decreasing, in some it was markedly increasing. As far as could be gathered from statistics and other sources, the various forms of insanity showed a sinister increase. The heterogeneous group of diseases which went by the name of neurasthenia was increasing

at an alarming rate. Many authorities thought that cancer was more frequent than ever before, it was certainly not decreasing. The great pandemic of influenza of 1918-19 swept across the world, destroying millions, yet their knowledge of influenza had not increased, its etiology was disputed, its prophylaxis was ineffective, its treatment was almost nil. Rheumatic fever still exacted its heavy toll of damaged hearts. Most recent advance in diagnosis had centred on special tests. Science used them rightly, pseudo-science misused them. The tendency of modern diagnosis was to neglect the evidence furnished by signs and symptoms, and to place undue reliance on special tests. The time had not yet come—he doubted if it ever would come—when special tests alone would establish a diagnosis, except in a minority of cases. X-ray examinations stood in the forefront of these special tests. They had, however, their abuses as well as their uses. The fallacies were numerous in the hands of the inexperienced or uncritical. X-rays, by simplifying diagnosis, had made clinicians lazy. The limitations of X-rays were often not appreciated. There were lesions which they could not show. A negative radiogram was often found in a case of chronic appendicitis or of duodenal ulcer. Bacteriology and serology would be of more value in diagnosis if bacteriologists visited hospital wards more often and if clinicians were more familiar with the inside of laboratories. The last fifteen years had seen biochemistry rise into prominence. It had furnished many useful results, and had carried forward medical knowledge far. But for the clinical diagnostician biochemical tests were often useless, because in most cases the significance of the results rested on hypothesis, not on facts. A large number of renal function tests were both worthless and misleading, even when performed by experts. Biochemists and clinicians did not collaborate sufficiently. New methods of treatment had proved of great value when properly and appropriately applied. Yet almost every new line of treatment had been run to death—sometimes the death of the patient. Every new method had been hailed as a panacea, and applied to the cure of any and every disease. The result was that modern treatment was chaotic. The newest methods were not necessarily the best. Succeeding waves of fashion often dictated treatment. At one time oral sepsis was looked upon as the source of all evil, the dentists thrived, the population became edentulous, its ills remained. Then it was the appendix—that disreputable atavistic organ. The publicity booms which characterized every fresh discovery were to be regretted, they raised unfounded hopes, followed by undue scepticism.

Referring to the medical curriculum, Dr Syngo said that it had long been disputed whether a knowledge of Latin should be compulsory for the medical student. There were more medical terms of Greek than of Latin origin, yet Greek was not compulsory. In discussing medical terminology, Trousseau had said that people gave themselves a great deal of trouble to torture the Greek language and heap up learned solacisms. All the Greek and Latin roots used in medicine could easily be learned inside a week by anyone ignorant of both languages. Latin imparted culture, yes, but not the smattering necessary to enter a medical school. Medical knowledge was increasing in bulk at a great pace. Already the medical curriculum comprised five years at least of strenuous effort, crammed with excess of subjects and excess of material, the only consolation held out to the student being that future generations will probably be required to spend six or seven years in medical studies instead of five. And yet, was all this knowledge really necessary? Was a knowledge of the terminal arteries and small cutaneous nerves and ridges on bones essential to a working knowledge of anatomy? If anyone thought so he was quickly disillusioned at the first operation he witnessed. The average man who was going to spend his life in endeavouring to cure the sick was compelled to learn far too much anatomy. It was fatuous to spend two and half years in the study of anatomy. *Materna medica* was another subject which until recently—and, indeed, in some medical schools still—was overloaded with useless paraphernalia. It was in the prevention of disease that modern medicine had achieved its most dramatic results, yet this subject occupied a very small

place in the medical curriculum. Pathology and bacteriology received too little attention. It was clinical work, however, which suffered most in the present-day curriculum. On paper, three years were allotted to clinical subjects, actually, few students were able to devote more than one year's real work to the hospitals. No matter what branch of medicine, what specialty a man was going to take up afterwards, a practical knowledge of clinical medicine and surgery was essential. The aim of a medical school should be to teach, not only the essentials of medicine, but also the right principles and methods of adding to knowledge after qualification. For this a five years' course was ample, provided that it was not cluttered up with non-essentials. Constant revision of a medical curriculum was necessary. Conditions changed year by year. What was a good course to-day would probably be decidedly out of date ten or twenty years hence. The tendency of the present system was to produce a temporary cum knowledge of each subject, which was quickly forgotten after that particular examination was passed. The Irish School of Medicine had a world-wide reputation in the days of Graves, Stokes, Corrigan, and other distinguished masters. Dublin still offered to the student more facilities for clinical experience than were available elsewhere, every student might have the invaluable opportunity of being a hospital resident for six months. In Dublin, at least, the patient had not been buried beneath a heap of modern instrumentology and laboratory tests. They had rather gone to the opposite extreme. The great need was for more pathological, bacteriological, and biochemical facilities to aid them in research. The difficulty in obtaining post-mortem examinations was a serious drawback to advancement. Waves of knowledge had in the past been followed by tangles of ignorance. In the Dark Ages Hippocrates' works were read, the letter, and not the spirit, of his teaching was followed, medicine declined. To-day the physical sciences had opened up immense possibilities for medical progress, wonderful discoveries had resulted, previous notions and ideas had been eclipsed, the belief in the magical and the irrational had increased, because the critical faculty had been dulled by so many wonders. Belief in everything was followed by belief in nothing. Credulity was succeeded by scepticism, scepticism by cynicism, cynicism made no effort, knowledge declined. People, dazzled by to-day, talked as if the millennium of science had come. This was a superficial view. Modern science made them more conscious than ever of the depth of human ignorance and of the great field which lay before them. Hard and conscientious work, accurate observation, sound reasoning, a mind free from obsessions and superstitions, a firm belief in the possibilities of medicine as an art and as a science—these were the things that had raised medicine to its present greatness, these were the things that would carry it onwards, always.

ULSTER MEDICAL SOCIETY

The second meeting of the Ulster Medical Society was held in the Medical Institute, Belfast, on November 5th, when Mr J. A. Craig, the president, was in the chair. Professor J. E. MacIlwaine read a paper on hyperpiesia, the essential hypertension of Allbutt. He dealt with the physiology of blood tension, quoted a number of statistics showing the average results of observations, and outlined some experiments. Clinical evidence showed that arterio-sclerosis and high blood pressure were not invariably associated. It was possible to have one without the other. The relationship of hyperpiesia with endocrine glands, with toxicity, with the menopause, with heredity, and its association with vascular neuroses in early life, were described, and its diffused variability was likened to neurasthenia. The chief symptoms were mentioned, cardiac pain and oppression, pain in the upper abdomen, vertigo, lack of concentration, and, in the end, signs of the breakdown of the myocardium. The duration of life was very variable. In treatment he favoured more general constitutional methods than the administration of vaso dilators. Dr Boyd Campbell read a paper on the prognosis and treatment of aortitis. Any infection might cause the affection, but a syphilitic was by far the commonest, it accounted for 80 to 100 per cent. It was often

complicated by incompetence, but never by aortic stenosis. Pain coming on without emotion or exertion, especially at night, a feeling of constriction or pain at the upper end of the sternum, dyspnoea on slight exertion and paroxysmal, variable cough on lying down, were the most characteristic, early fatigue and vertigo were the same as in other forms of cardiac disease. The characteristic physical signs were a sallow, septic look, abnormal pulsations in the supra-sternal region, increase of the dull area, change in the x-ray shadow, and a peculiar changing second aortic sound which was not lost when incompetence supervened, high blood pressure was not present. Dr Campbell divided the stages into three—early, moderately advanced, and advanced—and presented then diagnostic differentiation. In his cases the average length of life was five years, and the majority of the patients were in the fifth decennium. He gave, perhaps, a preliminary course of iodine and mercury, and then small doses of arsenic, and insisted on absolute rest. Dr McKisack, Professor John Milroy, Dr Colwell, Professor Thomson, Professor Fullerton, Dr Houston, and the President all discussed the papers.

Correspondence.

PREHISTORIC TREPHINING

SIR,—In your interesting annotation on prehistoric trephining (November 7th, p. 857) it is stated that Dr Wolfel has come to the conclusion that this operation was performed by prehistoric surgeons as a procedure for the treatment of depressed fracture of the skull. He based his conclusion on the fact that certain crurs—for example, South America and Melanesia, where the operation is still performed among savage races—are areas in which clubs are used as weapons of war. His argument appears to be as follows. As the clubs and the trephinnings occurred in the same districts, it is a case of cause and effect, the clubs produced the fracture and the trephining was adopted as a treatment. This to me does not seem a very conclusive argument, and a good deal more evidence would be necessary before it could be held that Dr Wolfel's thesis is proved. In my opinion he is wrong in drawing any conclusion as regards prehistoric trephining from these modern operations by savages. I should like briefly to argue the question and to examine the evidence.

In the collection of Peruvian skulls, numbering about 1,000, made by Dr Murry of the Peruvian army, nineteen have been trephined. These skulls are almost certainly very much later than the Neolithic period. In some of them the method of trephining was different from that of the premetallic surgeon, who made an oval or circular hole. The Peruvian skulls in certain instances show four linear incisions, the resulting piece of bone being rectangular. In one of these skulls there is a depressed fracture of the left temporal bone, such as might have been produced by the impact of a club. The operation of trephining has been begun but not completed, probably on account of the death of the patient. Three other skulls show evidence of fracture, and we may therefore agree that in the Peruvian skulls the operation was probably carried out as a surgical procedure for the treatment of depressed fracture. But when we come to the most ancient of trephining operations—those of the Neolithic period (and this is the period generally referred to by the expression "prehistoric trephining")—there are no facts to support him.

In the enormous collection of skulls found in France, where by far the greater number of ancient trephined skulls has been obtained, there is no evidence that the operation was performed for any surgical reason. To argue that because clubs are used by savages and trephining has sometimes been carried out by them for depressed fracture produced by the clubs, therefore the same obtained in the new stone period, where in an immense collection of skulls there is not a single one with signs of such a fracture, is fallacious. Dr Wolfel's theory is totally unproved and has no basis of fact to support it.

It has been urged by competent archaeologists that the

operation was carried out for various nervous disorders, such as convulsions, delirium, epilepsy, and insanity, which have always been considered indications of the possession of body and soul by evil spirits. There arose naturally the suggestion of making an opening in the body, the head by choice, to let out these evil spirits. Now what evidence is there in support of this? In the South Pacific islands a notion prevails that headache and other cerebral affections proceed from pressures of the skull on the brain. The remedy practised by the natives is a primitive method of trephining. This custom is so prevalent that very few of the adult males are without such a hole in the cranium. This race is in about the same state of civilization as the French Neolithic man of 4,000 years ago. This is certainly an argument in favour of trephining having been carried out by our remote ancestors for medical reasons. But allowing this assumption to be correct, it can only have applied to a very small number of instances, for even at the present time cases of nervous diseases sufficiently severe to justify trephining are quite rare. Much less would the operation have been required in those far-away savage days, when the necessities of modern life with its consequent train of severe nerve disorders was unknown.

I believe that the trephining of these ancient skulls was in the very great number of instances carried out for some ethical or religious reason. It is well known how throughout the ages the most varied and curious customs, many of them entailing severe mutilations, have prevailed as religious observances. No great stretch of imagination is required to bring this surgical procedure within the same category. The whole question is of course purely speculative, but I claim that so far no evidence whatever has been adduced in favour of its use by our Neolithic ancestors as a surgical operation for depressed fracture—I am, etc.,

Hove Nov 16th

L. A. PARRY, F.R.C.S.

RECURRENT DISLOCATION OF THE SHOULDER-JOINT

SIR,—The writer of the leading article in the current issue of the JOURNAL (November 14th, p. 911) apparently has not noticed that I described the pathology of recurrent dislocation of the shoulder-joint in the BRITISH MEDICAL JOURNAL of December 15th, 1923. This condition is not due to stretching or imperfect healing of a torn capsule, nor to weakness or lack of tone in the surrounding muscles, it is due to detachment of the fibrous capsule from the fibro-cartilaginous glenoid ligament. In most cases also the glenoid ligament is detached from the margin of the glenoid cavity. The reality of this essential lesion is not a matter of opinion, but of observation; and it can be verified by any competent surgeon who takes the trouble to look for it—I am, etc.,

London W 1 Nov 15th

A. S. BLUNDELL BANKART

* * It is regretted that in our leading article on recurrent dislocation of the shoulder no reference was made to the paper on this subject by Mr. Blundell Bankart in our issue of December 15th, 1923. Our article, however, had for its text a paper by Dr. T. Turner Thomas of Philadelphia. Mr. Bankart's very definite views as to the pathology and treatment of this disability are in contrast with those expressed by other authorities on this subject, and the discrepancy could perhaps best be accounted for by supposing that the conditions which he describes as found at operation are unusual. Burrell, Cotton, Turner, and others have all attributed the primary injury to a fall on the abducted arm, and have recorded a large number of successes after plication operations on the capsule. Several who claim that capsulorrhaphy is *per se* beneficial, yet admit that it is often followed by cure which, however, he attributes to other causes. It is difficult to believe that a number of competent surgeons have often exposed the joint cavity and failed to recognize the condition described by Mr. Bankart. It seems therefore probable that recurrent dislocation of the shoulder joint may be due to more than one kind of trauma and that it may exhibit more than one set of appearances and be curable by more than one procedure. The probability that this is so is

enhanced by the fact that capsulorrhaphy failed in a certain proportion of cases, and especially often in epileptics. The operation so ably devised and carried out by Mr. Blundell Bankart would appear to be certainly effective and probably the best for such cases as he describes.

PROFESSOR BLAIR BELL'S TREATMENT OF CANCER

SIR,—In answer to your inquiries, let me state, to begin with, that I have an absolute confidence in Professor Blair Bell and his work upon cancer, and let me give the reasons for my faith. Even the theory which underlies that work is in consonance with my personal views. So long ago as 1901, in an address given by me at Yale University on the "Causation of cancerous and other new growths," published in the BRITISH MEDICAL JOURNAL of March 16th of that year, I urged "that line of research which promises sure results and greater profit on the part of clinicians as well as of laboratory investigators lies in the direction of testing various methods of arresting the growth of the tumour cells without injury to the organism in general. Herein it seems to me that Coley has chosen the better part." And herein is the basis of Blair Bell's investigations.

Close upon five years ago, so soon as the first remarkable case of cancer of the breast treated by him was showing unmistakable signs of shrinkage, he honoured me with his confidence, I was shown the patient with the primary growth still not wholly absorbed, was given all the details of the treatment, nothing was kept back. I could not but be impressed by the vastness of the possibilities opened up, and the heavy responsibility should he publish this amazing case before the new method and its limitations had been thoroughly explored. I found that he had also taken into his confidence Mr. F. T. Paul, the well known Liverpool surgeon and authority upon cancer. Sir Charles Shearman, and Sir Robert Jones, and found, further, that he was willing and, indeed, anxious to place himself in our hands as an advisory committee. We asked and obtained his ready assent to the suggestion that nothing should be announced until he had treated fifty cases. He went further, and, while giving us free access to his cases, he offered to publish nothing that had not previously been submitted to us. It was under these conditions that his first paper was given out in the autumn of 1922.

We shied the responsibility for keeping back at this period the precise details of the treatment. Blair Bell's studies had led him to conclude that the most effective and least harmful form in which to administer lead was in a colloidal state, and at this period the preparations were safe for intravenous injection—that is, did not form precipitates—only within six or eight hours after they were made. They could not be distributed at a distance, they could only be prepared by experts under expert control. These fifty cases had shown that there was a very great variation in susceptibility to the drug, and it was not possible at this period to lay down precise details as to its safe use. There was, in short, so much still to be done from the standpoint of physical chemistry, pharmacology, clinical medicine, biology, and animal experiment that no one man, however industrious and however brilliant, could carry on the necessary laboratory investigations and at the same time maintain his practice and fulfil his duties as professor of gynaecology. Now it was that a group of generous and public spirited Liverpool citizens came forward and gave between them several thousand pounds to provide beds for poor patients, and to cover the cost of the needed laboratory investigations over a space of three years. Thanks to their generosity it has been possible to undertake team work upon a relatively large scale under the directorship of Professor Blair Bell. The term of some thirty members* includes several full time workers in various laboratories conducting researches under well known authorities, most of them heads of departments in the University, together with well known clinicians and members of the junior staffs of various hospitals. The members of the team meet every few weeks, receive discuss, and criticize freely the reports received

* The list of the members was given in Professor Blair Bell's paper in the LANCET last year (vol. 1 p. 267).

from different departments, and suggest new lines of inquiry.

The co-operation between the members has been remarkable, as again has been the co-ordination or harmony of the results obtained, clinical and laboratory. I lay stress upon these matters in order to impress upon your readers the conscientious and thoroughly scientific manner in which these investigations have been carried out, as again that the later phrases of Professor Blair Bell's investigations are the result of an amount of team work such as has never before been devoted to a medical problem in any one centre. The announcement by the Toronto correspondent of the *Times* that thus far 200 cases (or as a matter of fact a little under that number) have been treated in the course of the five years that have elapsed since the treatment was initiated is evidence of the care taken to study each case thoroughly and not to receive more patients than can be given this thorough study.

But it is peculiarly difficult at this juncture to speak freely about the results obtained. Professor Blair Bell left for America with the expressed intention of asking his audience at the Toronto Academy of Medicine not to discuss his address until it appeared in print here in England (in the *Lancet*). Evidently, notwithstanding his desire, it has been impossible to prevent certain of the results of his work finding their way into the public press. It has been equally impossible for his friends and co-workers here in Liverpool to deny the substantial accuracy of the cabled reports. The most that we can do is to beg everyone to wait until, as we hope, the full text of his two papers appears within the next fortnight—the one on the theory underlying his method of treatment, the other upon the methods and the results thus far obtained. As a matter of fact, the first of the two has appeared in the delayed *Lancet* of this week.

One other service we can perform—namely, to warn the public not to expect too much. It must, for example, be evident to every medical man that if a cancer is far advanced, and if either the primary or any secondary growth has extensively infiltrated and replaced the normal tissue of some important organ (such, for example, as the stomach), the very act of causing necrosis and deliquescence of the mass of cancer cells may be followed by a fatal gassing and rupture of the vessel involved, by perforation, hemorrhage, and the like. Granted that Blair Bell has discovered an agent which destroys the cells of malignant growths, it is only in relatively early cases where the primary growth does not involve what we may term a vital area—or, in advanced inoperable cases, where similarly by great good fortune neither primary nor secondary growths involve such areas—that the destruction and absorption of the cancer or sarcoma may be followed by restoration to good health. There can be, in the circumstances, no certain "cure" for cancer. At most we can look forward to a material reduction in the mortality. Even if this only can be accomplished it means much for humanity—I am, etc.,

Liverpool Nov 15th

J GEORGE ADAMI

PRE-CANCEROUS CONDITIONS

SIR,—The disappointment expressed in your leading article last week (p 912) is universally felt. We all regret that the evidence afforded by the visible pathological changes in the breast, or indeed of any other part, is not more conclusive.

The discussion to which you referred performed an important function. It demonstrated how limited is evidence based only on histological investigation. Evidence thus gained is essentially more or less speculative. Histological investigation and biological research, when combined, do not at present indicate a state of hyperplasia that will inevitably end in carcinoma. Yet the admission must be made that one or all of these states may be concerned in the carcinoma process. It must also be admitted that probably one state of hyperplasia is nearest to the culminating point of carcinoma.

In my share of the discussion I pointed out a particular state of epithelial hyperplasia that appeared to me to

be in that position. Rare opportunities occur where carcinoma cells can be seen streaming directly into the surrounding tissue from an epithelial hyperplasia in a duct. This particular type of epithelial hyperplasia within the duct resembles precisely that which I described as being the pre-cancerous state—I am, etc.,

G LENTHAL CHEATLE

RAW PANCREAS BY MOUTH COMPARED WITH INSULIN

SIR,—In reply to Dr Lawrence's letter (November 14th, p 920)

1 The diet was not rigid, the patients being allowed their normal diet but for the prohibition of sugar, potatoes, and foods rich in carbohydrates, such as beet. In fact, both patients were allowed substantial amounts of ordinary white bread after being on raw pancreas a short time, with no apparent ill results.

2 The blood sugar tests were always taken at the same time, three hours after breakfast—I am, etc.,

Preston, Nov 14th

J BERNSTEIN

FOCAL INFECTION

SIR,—It is now assumed that a focus of infection is the cause of many diseases of body and mind, but, surely, the evidence for this theory is inconclusive. It is certain that every unit in a civilized community is constantly collecting a bacterial flora, which becomes a permanent part of his body, we cannot estimate the effect of this until we have a standard of normality in bacterial infection. Such a standard could only be obtained by the bacteriological examination of the accessible passages of a large number of apparently healthy bodies. It is highly probable that such an investigation would materially modify our conceptions of infection, and it would certainly yield to the bacteriologist some interesting surprises.

At present all we know is that, if we look for a focus of infection, in many diseases we often find it. If this was shown to be present in the majority of presumably healthy persons, what becomes of its importance in etiology?

What makes the general practitioner sceptical is that he sees a very large number of people, with an obvious septic focus, who enjoy good health to old age, and, conversely, no septic focus can be found when it ought to be present—I am, etc.,

London, E 12 Nov 15th

A CAMPBELL STARK

ERRORS OF VISION AND AVIATION ACCIDENTS

SIR,—In your article on vision and aviation (November 14th, p 912) you rightly stress the importance of perfect vision and of perfect ocular muscle balance. I would, however, like to point out that I have two patients, both of whose names are famous as pilots, neither of whom has had an accident due to either his vision or muscle trouble, yet the first has a latent divergence, and 6/60 vision without glasses (he is myopic with some astigmatism) while the second has the left eye pushed backwards and downwards, the result of a gunshot wound of the orbit. This eye is to all intents and purposes blind, as he has fairly complete optic atrophy, while there is very little movement in the eye, owing to the derangement of the ocular muscles. Although he was so injured in the war, he has never made a false landing.

In 1902 Savage of America published a book on *Ophthalmic Myology*, dealing largely with the subject, and I have a set of *Biographic Clinics*, by the late Dr Gould of Philadelphia, dealing also with the same subject. Although one cannot agree altogether with all that they say (and many probably unnecessary muscle operations were performed for these defects in patients by our trans-Atlantic colleagues), undoubtedly, in many cases, uncorrected latent muscular defects may give rise to ocular symptoms and produce temporary diplopia. Against that, however, is the fact (and I have tested every patient's eye muscles that I have seen in private for the past sixteen

980 NOV 21, 1925]

CORRESPONDENCE

years, and think any practising ophthalmic surgeon will agree) that it is the exception to find perfect ocular muscles balance in anyone, just as it is to find an eye without some small error of refraction. But whether or not these defects give rise to symptoms entirely depends upon the nature of the work done, as a patient with a small amount of latent divergence of eye muscles and slight far-sighted astigmatism may have no symptoms whatever, leading a normal outdoor existence, but the defects may cause trouble, eye-strain and headache, if he be compelled to use his eyes much for near work. Similarly, he may have no error of refraction, but some degree of muscular trouble, which causes strain, and he is unable to converge and causing objects near at hand without one eye diverging and causing diplopia. These defects are generally associated with an error of refraction, however, and the usual thing is to find that the hypermetropic eye has an excess of convergence (not a disadvantage altogether in near vision), while the short-sighted eye generally has an excess of divergence. These defects are generally latent but become manifest in certain conditions, just as a small degree of astigmatism may or may not give rise to symptoms. It may be that fatigue or increasing age prevents the patient from correcting the defect himself—I am, etc.,

SIDNEY TIBBLES

London W. Nov 14th.

PREVENTION OF THE COMMON COLD
 Sir,—In your report (November 14th p 901) of the meeting of the Medical Officers of Schools Association, and your remarks thereon (p 913) you refer to hygienic and other precautions to prevent cold-catching. I think it would be well to emphasize one point which in my experience is of great importance. I refer to the avoidance of household dust. I have seen many instances of the development of an acute coryza through exposure to such dust. I will give two examples.

A lady who is very subject to catarrhs has several times traced an attack to dusty bedding or floors in boarding-houses and hotels where domestic attention is faulty. A superior mechanic on two occasions had to execute repairs in an exposed bungalow at the seaside during cold stormy weather. The bungalow was exceptionally clean, and he remained free from colds, but each time developed a severe one a few days after returning to dusty home quarters. Where other forms of infection are also present, it is still more important not to stir up the dust. A postmaster was under my care for tuberculosis some years ago. He came from an office where there was a possibly phthisical clerk in the next room, and the postmaster usually arrived just after the floor had been swept in the ordinary way.

I could mention other suggestive cases but fear to occupy too much of your space. Polished floors in hospitals and sanatoriums are a great help in preventing catarrhal attacks of all kinds, but only if the dust be not stirred up—I am, etc.,

F. R. WALTERS

Crook Farm Sanatorium, Farnham Nov 1th

OSTEOPATHY AND CHIROPRACTIC

Sir—Dr C O Hawthorne's letter in your issue of November 14th (p 921) contains a misquotation of the Warrington motion brought before the Representative Meeting at Bath. No doubt this has been due to an unintentional slip, but as it is of importance for accuracy of argument I draw attention to it. He writes in his first paragraph "And 'that no unqualified person be allowed to practise medicine or surgery.' If he refers to the agenda he will see that the motion stated that 'no unregistered person be allowed to practise medicine or surgery.' There is a distinct difference between an unqualified person and an unregistered person, and the motion was drafted so as to bring practitioners of general medicine on a parallel with practitioners of dentistry. Under the Dentists Act a person cannot practise dentistry unless he

is registered, no matter how well qualified he may be to extract teeth or fit dentures.

Registration is for disciplinary purposes and there are "prosecutions and penalties" for the practice of dentistry by unregistered persons no matter how well qualified they may otherwise be. After the passing of the Dentists Act large numbers of unqualified dentists of good character were admitted to the *Dentists Register*, thus giving them a legal qualification to practise dentistry.

If the Legislature should ever restrict the practice of medicine to registered persons—and the practice of medicine could never mean the casual prescribing of somebody's pills, and liniment by a kindly curate or by my Lady Bontal, although it might mean systematic shrine healing—then without doubt all manner of healers would clamour for admission to the *Register*, and by this means receive legal status and official recognition.

The point about the present controversy is that the osteopaths are seeking this status and recognition before there is any restriction on their right to practise. For some time previous to the Bath meeting it was generally well known that the osteopaths were using such influence as they have on members of Parliament to secure registration, but no one, I suppose, realized that the danger of their success was so imminent until Dr E. Graham Little's warning.

The Warrington motion was, I agree, too definite and drastic for practical politics at the present time, but it could have been amended or referred to Council or considered instead of being talked out in an amusing speech of humorous contempt by Dr Hawthorne—I am, etc.,

J. S. MANOY

"THE STRAIGHT SPINE"

Sir,—There is one point which has not been touched upon in connexion with "the straight spine" so ably advocated by Major Austin in the *British Medical Journal* of October 24th (p 769). It is as follows.

The muscles which play a major part in maintaining the erect attitude are the transverse short muscles of the spine. When standing with a straight spine, and little if any lumbar hollow, these muscles are brought into play and will strengthen with use. When standing with a full lumbar hollow the attitude known in my boyhood's days as "the Grecian bend" a certain amount of support is gained by the locking of the pelvis. This attitude does not are thus far not called into play. This attitude does not therefore tend to strengthen the back muscles to the same extent as is done by the straight spine—all

With regard to the attainment of a straight spine—that is necessary is to rotate the anterior part of the pelvis upwards so that the pubes come to lie at a higher level. This compels obliteration of the lumbar curve. On the other hand, allowing the pubes to drop to as low a level as possible will accentuate it. This rotation of the front of the pelvis upwards will ought to be taught to all, and especially to girls, owing to their greater liability to a weak spine than is the case with boys—I am, etc.,

T. STACEY WILSON

Birmingham Nov 13th.

MEDICAL MANIFESTOS

Sir,—During the past ten days I have received circular letters from two medical bodies. Each body proposes to issue a memorial or manifesto. One states that agreement will be assumed unless dissent is made. The other end thus "If I do not hear from you by return of post I shall conclude that you are willing to allow your name to be published in this connexion." And accordingly the names of non-committed men will be attached to a manifesto to the lay press which begins "We, the undersigned,"

It seems to me that this procedure is wrong and that if it be allowed medical manifestoes will be treated with contempt—I am, etc.,

London W 1 Nov 12th.

N. BISHOP HART

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT]

PARLIAMENT resumed on Monday, November 16th, to complete business outstanding at the August adjournment, and is expected to sit till about December 18th. The Lords had no business but the Commons were faced with a full programme, including many departmental bills, some of medical interest.

The *Expunging Laws Continuance Bill* was read a second time on Monday and passed through Committee next day. Among the measures which it continues are the Coroners (Emergency Provisions) Act, 1917, the National Health Insurance (Prolongation of Insurance) Act, 1921, Section 3 of the National Health Insurance (Cost of Medical Benefit) Act, 1924, and Section 54 of the National Health Insurance Act, 1924.

The list of bills down for consideration before Christmas is very heavy. The Lead Paint (Protection against Poisoning) Bill is one of special medical interest, but conflict is chiefly expected over the Rating and Valuation Bill and a special Insurance Bill proposing new import duties, which may include duties on imported cutlery and surgical instruments. The Opposition is also claiming time for several general debates. Mr Ramsay MacDonald has suggested that there should be a general discussion on the cases where war pensions are refused on the ground that the disability does not result from war service.

The Medical Committee of the House of Commons held an inaugural dinner on Monday. Sir Lenthal Cheate, who was a guest, gave an address in which he argued that the Minister of Health should always be a medical man. The Committee discussed this suggestion at length, but could not agree upon it, some members pointing out that much of the work for which the Minister is responsible is administrative rather than medical.

Supply of Insulin in Scotland

The question of the distribution of insulin was raised in the House of Commons on Tuesday, November 17th, on consideration of the Public Health (Scotland) Amendment Bill, on the Report stage. The measure authorizes local authorities under the Scottish Public Health Act of 1897 to make arrangements for providing medicines and treatment to persons suffering from diabetes.

Dr Shiels moved at the end of Clause 1, which is the operative clause an amendment providing that the Scottish Board of Health should require the local authority to arrange that any medicine used for the treatment of persons suffering from diabetes and who in the opinion of the local authority required assistance in obtaining such medicines and treatment, should be dispensed by a registered pharmacist or by a registered medical practitioner. He urged that insulin should be distributed under medical supervision. That precaution, he said, was already taken by the Poor Law authorities and under the National Health Insurance Acts. He did not see why the poor people who were to receive the insulin under this bill should not have the same definite safeguards as others.

The Secretary for Scotland (Sir J. Gilmour) declined to accept the amendment. Everyone wished the greatest safeguards to be observed in the use of this drug. It was manufactured in bulk and sold in closed capsules. It was prescribed by a doctor and at a certain stage of the treatment it might under careful medical directions, be administered by the patient himself. So far as its purity was concerned, it did not matter whether it was handed by the local chemist over the counter or dispensed by the local authority at its clinic. It could not be said that the risk of its being mishandled was any greater under the bill than in the way proposed by the amendment. It was desired that the Scottish Board of Health working through the local authorities should be able to dispense insulin at a price which would bear a fair comparison with that at which it could be obtained from a chemist's shop. The chemist would of course have to make a certain profit.

Sir A. Sinclair asked whether there was any risk of deterioration and whether chemists having been able to detect this had not rejected some of the supplies. Sir J. Gilmour said deterioration of the drug could not be detected by the local chemist.

Mr Westwood asked for a guarantee that only those persons properly qualified under the Pharmacy Acts should be allowed to manufacture insulin.

Sir John Gilmour said that he appreciated very much the natural and proper desire of members to see that every precaution was taken in regard to the manufacture of this article. He could give a guarantee that it was manufactured directly under the supervision of the Medical Advisory Council. So far as the handling and manufacture were concerned it was done by properly qualified people. The bill dealt not with the manufacture, but the distribution, which was made in glass capsules so that the drug was properly protected.

Dr Shiels's amendment was then rejected without a division. On the motion for the third reading of the bill, Mr W. Adamson said that although the Labour party supported the bill, they regretted that it was limited in its scope. The measure should have been extended to other diseases to bring the administration of public health in Scotland into line with England. An effective remedy might be found for cancer at any moment and it would be a tragedy if the poor people of Scotland could not get the remedy because of its costly nature.

Sir J. Gilmour said that he appreciated the support of the Opposition in regard to the bill. The problem of cancer was of such magnitude and so important that it should be dealt with when it arose. If a solution of the problem was found there could be no doubt that Parliament would deal with it adequately.

The bill was then read a third time and passed.

The Navy and Army Medical Services—Sir L. Wothlington Evans stated on Monday that the pay and conditions of service of medical officers in the Navy, Army, and Air Force were being examined by an interdepartmental committee which had authority to take evidence from outside the Government service and would be understood obtain the views of the British Medical Association.

Notes in Brief

Schemes for the improvement of unhealthy areas have been submitted by seventy local authorities since 1919. The schemes numbered ninety one, and eighty two have been confirmed.

The Prime Minister has announced that the bills to an end the Factories and Workshops Acts and the law with regard to the use of road vehicles will not be taken this session.

Obituary.

GEORGE REID, M.D., O.B.E.,

Consulting M.O.H. Staffordshire County Council.

THE announcement we had to make last week, that Dr George Reid had died after a long period of ill health will have been received with great regret by those who knew the excellence of his work as medical officer of health for Staffordshire and had come under the influence of the charm of his personality.

He was born in Aberdeen in 1854. He graduated M.B., C.M. in the university of that city, and took the M.D. degree in 1881. In 1875 he became house-surgeon to the Staffordshire General Infirmary, two years later he entered on private practice and was appointed honorary physician to the infirmary. At the time of his death he was consulting physician. He early turned his attention to public health and was appointed medical officer of health for the Stafford Rural District. The Local Government Act, which authorized the appointment of medical officers of health to counties, was passed in 1888, and in the following year Dr Reid became medical officer of health for Staffordshire, his was one of the earliest of such appointments made. He held the office for thirty-three years. One of the most important matters on which he was called upon to advise the Public Health Committee of the county council was the prevention of the pollution of rivers, upon which the local authorities of the county eventually expended large sums of money, being rewarded by a considerable measure of success. He became a recognized authority on the subject, and gave evidence before the Royal Commission on Sewage Disposal. He also gave much attention to questions of industrial hygiene, and in 1908 was a member of the Departmental Committee on the use of lead in pottery. Later on, as school medical officer for the county, he was responsible for the institution of medical inspection of schools, health visiting, and school nursing, and for the establishment of infant welfare centres in the county. He devised what is known as the pavilion type of elementary school building, which was approved by the Board of Education and has been extensively adopted both in this country and abroad. He was also concerned with the introduction of the organized work in the county for the prevention and treatment of tuberculosis, and was medical officer to the Staffordshire, Wolverhampton, and Dudley Joint Committee on Tuberculosis.

Dr Reid became a member of the British Medical Association shortly after obtaining his first degree, he was general secretary of the Staffordshire Branch from 1888 to 1894, and financial secretary from 1896 to 1900. He was president of the Birmingham and Midland Counties Branch in 1895 and of the Staffordshire Branch in 1907, and took part in the central affairs of the Association as a member of the Parliamentary Bills Committee, he was vice-president of the Section of State Medicine at the Annual Meeting in 1898 in Edinburgh, and president of the Section of Medical Sociology at the Annual Meeting in 1911 in Birmingham. He had also been president of the Society of Medical Officers

of Health, of the Midland Counties Society of Medical Officers of Health, and of the Association of Sewage Disposal Works Managers.

During the war he was advisory sanitary officer to the North Midland Brigade, but he was handicapped all through his life by ill health, and after about a year's service he was invalided. In February, 1922, he was compelled to resign the county medical officership, and was appointed consulting medical officer. He went to reside at Cheltenham, where only a few weeks ago his wife died, and Dr Reid was staying with his brother, Dr Charles Reid, physician to the Staffordshire General Infirmary, at the time of his death on November 6th. He is survived by a son and a daughter.

The funeral took place at Cheltenham on November 10th, Dr Ridley Bailey, chairman of the Public Health Committee of the British Medical Association, and a member of the Council of the Society of Medical Officers of Health, had intended to be present, but was prevented by indisposition.

ROY CHARLES MERRYWEATHER, M.R.C.S., Perth, Western Australia

Details have recently reached us of the death of Roy Charles Merryweather, which took place suddenly on July 21st, 1925, at Perth, Western Australia. He had been apparently in good health, and was at work until a few minutes before his death, which was due probably to angina pectoris.

The son of a doctor practising at Guisborough in Yorkshire, he was born in 1880, and received his medical education at University College and Hospital, London. He was very popular as a student, and became honorary secretary, and later vice-president, of the Union Society. He was good at all games, and was a member of the team which won the inter-hospital association football cup in 1900. He gained the Fellowes medal in clinical medicine. After taking the diplomas of L.R.C.P. and M.R.C.S. in 1903, he held the posts of house-physician at the Brompton Hospital for Consumption and Diseases of the Chest, house physician (to Sir Thomas Barlow) at University College Hospital, and assistant medical superintendent to the Brompton Hospital Sanatorium at Fimley.

After practising for a short time at Great Yarmouth, Merryweather left England for Australia in 1908, and entered into partnership with Dr William Trethowan at Perth, Western Australia, where the soundness of his judgement, the wideness of his knowledge, and the keenness of his intellect soon brought him a deserved reputation as a skilled physician, and determined his success in a very large practice. Early in his Australian career he was appointed honorary physician to out-patients at the Perth Public Hospital, and at the time of his death was the senior honorary physician. He took a very active part in the work of the Western Australian Branch of the British Medical Association, and was president of the Branch in 1916. He acted as delegate of the Branch at the Annual Meeting at Cambridge in 1920.

Roy Charles Merryweather was not only a skilled physician, he was a man of deep sympathy, a charming companion, a true and loyal friend. He leaves a widow and three children to whom we offer our sincerest sympathy in their great loss.

LANCELOT NEWTON, M.R.C.S., Alconbury Huntingdonshire

We regret to record the death from cerebral haemorrhage, on November 10th, of Dr Lancelot Newton of Alconbury Hill Huntingdon. Dr Newton was the senior medical practitioner in the county. He was born at Alconbury on November 7th, 1846, and was educated at Epsom College and at St Bartholomew's Hospital, where he was a prize-man and prosecutor to the Royal College of Surgeons. He took the diplomas of M.R.C.S. and L.S.A. when he was 21, and practised at Alconbury Hill till 1911, when he retired. At the outbreak of the great war he returned to practice, and continued till December, 1918. During this period he had charge of three camps for German prisoners of war,

in addition to his other extensive duties. Dr Newton was medical officer of health to the Huntingdon Rural District Council up to the time of his death. He was an active member of the British Medical Association, and served in the offices of president of the Cambridge and Huntingdon Branch and chairman of the Division. He was also chairman of the Panel Committee, of the Military Service Tribunal, and of the Medical Service and Medical Benefit Subcommittees, and he acted as secretary of the Panel Committee during the war. Dr Newton was an Oddfellow, and held office in the Foundation of Friendship Lodge at Alconbury. He was a vice-president of the Cambridge and Huntingdon Archaeological Society, secretary of the Huntingdonshire branch of the Bible Society, and people's warden at Alconbury Church for many years. Dr Newton leaves a widow and three daughters. He was of a genial and kindly disposition, and was beloved and respected by all with whom he came in contact.

We regret to record the death, on November 1st, of Dr GEORGE LUCAS PARDINGTON, consulting physician to the Tunbridge Wells General Hospital, who had practised in that town for many years. He received his medical education at St Bartholomew's Hospital, and obtained the diploma of M.R.C.S. in 1878, and those of L.R.C.P. and L.S.A. in 1879. In the following year he graduated M.B. of the University of Durham, and proceeded M.D. in 1882. In 1903 he obtained the M.R.C.P. Lond. After holding the post of house-physician to the General Lying-in Hospital at Lambeth he settled at Tunbridge Wells, became a member of the visiting staff of the hospital there, and engaged in general and consulting practice. While a student at St Bartholomew's he had collaborated with the late Sir Lauder Brunton in a research upon the influence of quinine and sulphuric acid on reflex action, which they recorded in the *St Bartholomew's Hospital Reports* for 1876, in subsequent years he published several practical papers on hydrotherapy, massage, and kindred subjects. Dr Pardington was for a considerable time a member of council of the Section of Balneology and Climatology of the Royal Society of Medicine, and after serving as vice-president was elected president for the session 1920-21, when he took for his presidential address the subject "Advancing years and balneotherapy", a full report appeared in our issue of February 5th, 1921 (p. 183). He was an authority on balneology, to which he had devoted much of his time, not only had he a very full knowledge of the medical aspect of the subject, but he had visited nearly every Continental health resort, so that he was also well acquainted with the best conducted and most suitable hotels, and thus was able to advise his patients on the subject. Dr Pardington was essentially a man of the world, with a wide practical knowledge of medicine, enhanced by his keen powers of observation and a natural ability for putting facts in their proper relative positions. Added to this was a kindness of nature and a great power of sympathy. He was a fine scholar, a keen sportsman, a good shot, and a good judge of gun dogs.

Dr H. R. CARTER, Assistant Surgeon General of the United States Public Health Service, who died at Washington on September 14th, was director of the hospitals of the Panama Canal zone from 1904 to 1909. He was closely associated with the campaign in the United States for the eradication of yellow fever and malaria.

Dr B. NAUNY, formerly professor of clinical medicine at Strasbourg, whose work on cholelithiasis was translated into English in the New Sydenham Society's publications, has recently died at the age of 85.

Dr OCTAVE LEFEBVRE, a well known Belgian ophthalmologist, recently died of an attack of angina pectoris as he was finishing an operation for cataract at the Charleroi hospital.

Universities and Colleges.

UNIVERSITY OF OXFORD

At a congregation held on November 14th the following medical degrees were conferred

MD—D F Chapman N A Sprott

UNIVERSITY OF CAMBRIDGE

At a congregation held on November 14th the following medical degrees were conferred

ROYAL COLLEGE OF SURGEONS OF ENGLAND

An ordinary council meeting was held on November 12th, when the President, Sir John Bland Sutton, was in the chair

Diplomas of Membership were granted to 204 candidates. (The names were included in the report of the committee of the Royal College of Physicians of London, printed in our issue of November 7th p 871.)

Mr James Shierren was appointed a member of the committee of management in the vacancy occasioned by the retirement of Sir Charles Ballance

Mr Norman Leslie Capener, F R C S, was appointed the third Streetfield Scholar the subject of his research being 'The connection of the prostate gland'

Court of Examiners occasioned by the resignation of Mr Hngh Lett will be filled up at the ordinary council meeting on December 10th

Medical News.

MR G R GIRDLESTONE will lecture for the Fellowship of Medicine on tuberculosis of the spine on November 23rd at 5.30 p.m., in the lecture hall of the Medical Society of London, 11, Chandos Street, all members of the medical profession are welcome. Courses begin on November 23rd in medicine, surgery, and gynaecology at the Royal Waterloo Hospital, in nervous diseases in the out patient department of the West End Hospital, 73, Welbeck Street, and a late afternoon course (4.30 to 6) for general practitioners at the London Temperance Hospital. From November 30th to December 15th the Infants Hospital will hold a special afternoon course, on the Sunday a morning visit will be paid to the Thavies Inn Clinic. Afternoon lectures and demonstrations will be given by Dr Eric Pritchard and other members of the staff, and visits will be made to the Nursery Training School, Hampstead Garden Suburb, and the Home for Blind Babies, Chorley Wood. The Hampstead General Hospital has also arranged a late afternoon course for general practitioners from December 7th to 19th covering medicine, surgery, and the special departments. There will be a course in dermatology at the Blackfriars Hospital for Diseases of the Skin from December 7th to 19th, instruction will be given in the out patient department, and venereal clinics twice weekly. A copy of each syllabus and the Fellowship general course programme will be forwarded on application to the Secretary to the Fellowship, 1, Wimpole Street, W 1.

THE American Medical Association has called into being a "Council on Physiotherapy" to define the scope of physical methods in diagnosis and treatment, including the various electrical and mechanical contrivances. The council consists of two experts in physics, four clinicians, two physiologists, and two pathologists, together with the secretary of the association, and the editor of the journal. At the first meeting of the council a committee was appointed to prepare a series of reports on therapeutical methods and the apparatus used, while other committees are taking up questions of organization and education. Many manufacturers of apparatus have promised to co-operate. The inquiries under taken by the new committee will be extended to the therapeutic methods of massage, manipulation, hydrotherapy, and physical exercises.

PROFESSOR F G PARSONS, F R C S, F S A, will give a lecture on the earlier inhabitants of London, in the Governors Hall, St Thomas's Hospital, Westminster Bridge S E 1 at 5 p.m. on Friday, December 4th. The

lecture will be illustrated by lantern slides, and skulls of the various peoples mentioned will be shown. Admission is free, without ticket.

At the meeting of the Zoological Society of London on November 3rd Dr H H Scott pathologist to the society, communicated a paper on some congenital malformations of the kidney in reptiles, birds, and mammals.

An institute of the history of science has recently been opened at the Florence Faculty of Medicine under the direction of Professor A Corsini, the well known medical historian. The institute contains collections of ancient surgical instruments, mortars, pictures, busts, journals, and the like.

The autumn dinner of the Irish Medical Schools' and Graduates' Association will take place at Pagani's Restaurant, Great Portland Street, W 1, on Wednesday, November 25th, at 7.30. Tickets (price 10s) may be obtained from Dr Peart, 5, Harley Street, W 1. The guest of the evening will be the Right Hon Charles Andrew O'Connor.

The annual dinner of the Medical Legal Society will be held at the Holborn Restaurant, London, on Friday December 11th, at 7.15. The chair will be taken by the President, the Right Hon Lord Justice Atkin.

THE Golden Square Hospital for Diseases of the Throat will, with its new extension, be reopened on Thursday, November 26th, by Mr Lionel de Rothschild, O B E. The hospital was founded by Sir Morrell Mackenzie in 1863. It has grown until it now occupies a considerable portion of the square whose name it has made familiar throughout the medical profession. The extension includes an enlarged special department with a new operating theatre and a ward to which children are admitted for minor operations.

THE League of Mercy has this year awarded £9,820 to extra metropolitan hospitals. In the last twenty years, the League has contributed through the King's Fund £368,034 to the London hospitals and £74,739 to hospitals outside London.

DR FREDLAY MURCHIE and Dr Theodore W Stallybrass, of the Middle Temple, were called to the Bar on November 17th.

THE College of Physicians of Philadelphia announces that the next award of the Alvanza prize, amounting to about 300 dollars, will be made on July 14th 1926 and essays intended for competition must be received by the secretary of the College by May 1st. These essays may deal with any subject in medicine, but must not have been previously published, they must represent some addition to knowledge and be based upon original or literary research. The prize for 1925 has been awarded to Dr Raphael Isaacs of Boston, Massachusetts, for an essay on the nature of the action of rays on living tissue. Further information may be obtained from the secretary of the College, 19, South 22nd Street, Philadelphia, Pa., U S A.

THE seventeenth Congress of the Italian Phreniatric Society was held at Trieste from September 24th to 27th, when papers were read by Drs Kobylinski and Vidoni on the constitution in psychiatry, by Dr Weiss on psychiatry and psychoanalysis, and by Drs Modena, De Paoli, and Moudini on the treatment of general paralysis. Trieste was chosen as the place for the next congress.

THE thirtieth Congress of French speaking Alienists and Neurologists will be held at Geneva and Lausanne from August 2nd to 7th, 1926, under the presidency of Professor Long of Geneva and Dr R Semelaigne of Paris, at the same time as the celebration of the centenary of Pinel's death. The following subjects will be discussed: Schizophrenia, introduced by Professor Bleuler of Zurich and Professor H Claude of Paris; Babinski's sign, introduced by Dr Tomnay of Paris; Treatment of mental disease by work, introduced by Professor Ladino of Geneva and Dr Demay of Clermont (Oise).

PROFESSOR ROGER, who had hitherto occupied the chair of experimental pathology in the Paris Faculty of Medicine, has succeeded Professor Richet in the chair of physiology, and Dr Bezangon, previously professor of bacteriology in the same faculty, has succeeded Professor Chaffard in the chair of clinical medicine.

THE twenty fifth anniversary of the foundation of the Hamburg Institute for Marine and Tropical Diseases was celebrated on October 16th.

ACCORDING to a recent census Vienna possesses 4,051 medical practitioners (1 doctor to 461 inhabitants), Graz 461 (1 to 331), and Innsbruck 189 (1 to 298).

A SMALL POX epidemic at Milwaukee has recently come to an end after lasting for four months. Of the 500,000 inhabitants 376 contracted the disease and 86 died. Of the latter 82 had never been vaccinated and the remaining 4 had not been vaccinated within the last twenty years.

THE well known zoologist, Professor Ehlers of Göttingen, recently celebrated his 90th birthday.

Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W C 1**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W C 1 on receipt of proofs.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the **JOURNAL** should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 9861, 9862, 9863, and 9864** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are
EDITOR of the BRITISH MEDICAL JOURNAL, Antiology Westcent, London

FINANCIAL SECRETARY AND BUSINESS MANAGER
(Advertisements, etc.), **Articulate Westcent, London**

MEDICAL SECRETARY, Mediscera Westcent London

The address of the Irish Office of the British Medical Association is 16 South Frederick Street Dublin (telegrams **Bacillus Dublin**, telephone 4737 Dublin), and of the Scottish Office, 6, Drumsheugh Gardens, Edinburgh (telegrams **Associate, Edinburgh** telephone 4361 Central).

QUERIES AND ANSWERS.

"E O" asks for the results of experience with the use of parathyroid extract in the treatment of paralysis agitans—the dose, mode of administration, and effect.

ENCEPHALITIS LETHARGICA

SURGEON REAR ADMIRAL J J DENNIS—If by "sleepy sickness" our correspondent means the condition officially designated encephalitis lethargica he will find the geographical distribution of notified cases (the unit of distribution being of course the administrative area) given in the Registrar General's weekly return of births deaths etc. To obtain the distribution for the first ten months of 1925 it would be necessary to add the weekly figures. Probably direct application to the Ministry of Health would enable our correspondent to obtain a summary of this year's figures. It may be remarked that the gross number of notifications is not large enough to allow of any sound inferences as to the significance of small local prevalences.

RECURRENT URTICARIA

"N L" writes: A woman of 40, multipara previously in perfect health has for a year suffered nearly every night with severe urticaria. The itchy lumps rise, too at any time of the day if she knocks herself even if she rests her forearm on something hard. Dietetic experiments, salol and other means to cure have all failed. I should be grateful for suggestions for treatment.

CARBON DISULPHIDE IN SEBORRHOEIC ALOPECIA

"J A L O" asks for information regarding the usefulness and the method of using carbon disulphide in the treatment of seborrheic alopecia of the scalp. He believes it is used in France for this purpose, but can find no references.

* * The chief advocate of carbon disulphide in the treatment of seborrheic and seborrheic alopecia is Sahorrand. "J A L O" will find a chapter on it in his *Entretiens Dermatologiques* (published in 1913) on pp 421-426. Sahorrand recommends a saturated solution of sulphur in carbon disulphide. He has also written on the same subject in his series of "Entretiens" (published in 1924) dealing exclusively with diseases of the scalp. The results which he claims for this remedy have, however, not always been obtained by other clinicians.

HYPODERMIC NEEDLES

DR. J. PIRIE (Camington Spa) asks where he can get reliable hypodermic needles that will not break off at the shaft. He has not been able to get pie war quality needles so far in England, and is thinking of trying a German make.

LETTERS, NOTES, ETC

SMALL-POX IN THE UNITED STATES

The incidence of small pox during the last quarter of a century in the United States and the evidence afforded of the value of vaccination are considered in detail in an article in the *Boston Medical and Surgical Journal* for September 3rd, 1925 (p 466) by Dr W F Draper, Assistant Surgeon General to the United States Public Health Service. He reports that the small pox death rate in the areas for which data are available was 1.9 per 100,000 in 1900 and 6.6 in 1902, whereas from 1905 to 1922 it ranged

between 0.2 and 0.9, and in 1923 it fell to 0.1. During the last twelve years the annual case rate in various States has ranged from 23 per 100,000 in 1916 to 100 in 1920 and 1921, which would indicate that in the whole country there was an incidence of between 25,000 and 106,000 cases each year. Although the death rates in some cities have been as high as 42 per cent, they are low compared with those of pre-vaccination times. In 1751, for example, small pox was introduced into Boston by a ship from Barbados. At that time Boston had a population of 15,684 of whom 5,998 had previously had small pox. During the epidemic 7,669 persons contracted the disease, 1,843 fled from the town to escape infection, so that only 174 were left in Boston escape infection. Dr Draper points out that in the case of the alleged failure of vaccination in Japan, so frequently quoted by anti-vaccinists there is ample evidence that such vaccination had been improperly administered, and that even so the epidemic singled out the unvaccinated and those who had not been revaccinated. Following the epidemic the Japanese investigated the value of vaccination and made their vaccination laws much stronger with the result that a striking decrease followed both in the incidence and in the death rate of small pox.

PREMATURE OSSIFICATION OF THE CRANIUM CONVULSIONS DEATH

DR. LACHLAN H. GILCHRIST (Pollokshields, Glasgow) writes: I recently attended a puerpera (full time) who was delivered of twins. Owing to ineffectual pains the first child which was little macerated, was brought away with forceps. On examining for the second I had difficulty in feeling the anterior fontanelle, and a hard ridge could be made out running posteriorly. The child seemed all right at birth, the shape of the head, however, reminded me of the moulding seen in a brow presentation. Fits ensued within the first twenty-four hours and gradually a regular status epilepticus terminated the condition within forty-eight hours.

I obtained permission to examine the infant, and on reflecting the scalp I discovered that the cranial bones presented a marked degree of ossification. The anterior fontanelle was merely a crevice bridged over by a tough fibrous membrane—the metopic suture was fast disappearing and so was the posterior fontanelle. Where the line of overlap between the parietals at the sagittal sulcus is normally to be found there was a hard calcified ridge and if there had been only a single child with a large head I imagine the dystocia might be difficult to deal with anyone feeling that peculiar ridge, however, and knowing that the child would not live might be justified in thinking of craniotomy if things were very bad.

The convulsions, I take it, ensued as the intra-cranial pressure rose under the conditions of extrauterine life—the plates were of remarkable density for a newborn infant. I am curious to know of the incidence of this condition, especially as a cause of obstructed labour and infantile convulsions.

STERILITY IN THE MALE

DR. J. BARKER SMITH (London, S.E.) commenting on the article by K. M. Walker on sterility in the male (referred to in the *Eptome*, September 19th, para 201), suggests that the custom of taking sodium sulphate as a daily aperient in preference to magnesium sulphate may have an effect on spermatogenesis. According to some biologists magnesium induces fertility in plants and animals, while its absence causes sterility. In a recent case of sterility investigated by him the husband's semen contained no spermatozoa, and he had been taking Glanher's salt regularly.

HUMANISM IN MEDICINE

DR. RICHARD GILLIBARD (Willesden Green, N.W.) writes: In the *JOURNAL* of October 24th there are two noteworthy utterances, and I hope signs, on medical education. Professor John Fraser "would make great sacrifices to take an arts course before commencing a study of medicine." At the Harveian Festival it was said of Clifford Allbutt that he not only had "added greatly to the knowledge of medicine, but he was above all things a friend, a wise counsellor, and an upright and kindly gentleman." Is the profession to day in danger from falling from this level? With the advent of recruits from the commercial world into it with the inevitable limitation of specialism, to retain the character it is essential to cherish ideals. That can only be realized by a liberal education, whether logic, as an example, suggested by Professor Fraser or literature to illuminate. Without it in "medical amenities" and publicity in deliberations of policy, the magnanimous and larger view will be beyond our ken.

GENERAL PRACTICE TO DAY

"ANOTHER JUNIOR G.P." writes: With reference to the letter from Junior G.P. (November 14th, p 928) I agree that county council fees for dealing scientifically with abnormal labour are quite inadequate. Two guineas was reasonable when midwives were ill trained and doctors dealt with nine normal cases to one abnormal, but now when all doctors' cases are abnormal, difficult and anxious, fair remuneration would be at least four guineas, if not five or six.

VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 42, 43, 44, 45, 48 and 49 of our advertisement columns and advertisements as to partnerships, assistantships, and locum tenencies at pages 46 and 47.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at pages 179 and 180.

Report

OF

A SUCCESSFUL CASE OF EMBOLECTOMY,

WITH A REVIEW OF THE LITERATURE

BY

GEOFFREY JEFFERSON, M.S. Lond., F.R.C.S.,

HONORARY SURGEON, SALFORD ROYAL HOSPITAL, LECTURER IN
APPLIED ANATOMY, UNIVERSITY OF MANCHESTER

Cases of embolism in which the plugged artery has been opened and the clot removed with complete success are sufficiently rare to make records of single cases worth the making. The clarification of our views on this subject has largely come about through Eliar Key of Stockholm, whose masterly paper (1922) has done much to advance the surgical treatment of embolism. It is interesting to note that, whereas prior to 1922 only thirteen successes could be claimed out of forty-five cases, no fewer than fifteen successes have been obtained in twenty-eight cases published since that date. The result of the local teaching of Key is reflected in the literature of "embolectomy," which has been until now almost a Scandinavian operation. Pioneer work was done in England by Handley, Moynihan, Brodman, and Gordon-Watson, though their cases were less fortunate in result than that now chronicled.

J. E. male, aged 42, a patient of Dr. Gray of Lydesley, was admitted to the Salford Royal Hospital under my care for the radical cure of an umbilical hernia. The hernia was small and contained a little omentum only. The patient was well built, rather obese, but was in excellent general health. He had had no serious illnesses. The heart was normal, the pulse 80, and the urine free from abnormal constituents.

On April 23rd, 1925, radical cure of the hernia was performed by the resident surgical officer, Mr. R. L. Galloway. A transverse elliptical incision $3\frac{1}{2}$ inches long was made, the neck of the small hernia defined, the sac opened, a lobule of omentum which was lightly adherent was pulled down and ligatured off. The sheath of the rectus was incised and the deficiency repaired. The operation lasted from 3 to 3.15 p.m., and was performed without tearing or bruising. This wound healed by first intention, without any sign of local contusion.

Pre-op.—A quart of a grain of morphine tartrate was given at midnight to allay such pain as the patient had. The next morning he looked and felt well. At 5.15 p.m. on this day, twenty-six hours after the conclusion of the operation, whilst being moved in his bed by the nurses, who were straightening the drawsheet, he complained of a tingling sensation of "pins and needles" in the left arm, with increasing numbness. This rapidly developed into an intense pain, with complete paralysis of the arm. I saw him one hour later.

The man was very much disturbed at the sudden paralysis of the limb, and still more so by the pain which accompanied it. The arm was blanched, cold, and pulseless, insensitive to touch, and completely paralysed below the elbow. Feeble movements of flexion and extension were possible at the elbow joint. On tracing the line of the vessels up the arm pulsation was finally detected high in the axilla, but was not very clear. The man was stout and palpation not easy. Lodgement of an embolus about the termination of the axillary or commencement of the brachial artery was diagnosed, and operation advised. This was eagerly accepted by the patient, who was exceedingly disturbed at his misfortune and in a very agitated state.

At 7.45 p.m., two hours and a half after the embolism occurred, operation was undertaken under novocain and adrenaline infiltration. An incision 4 inches long was made over the axillo-brachial junction and the vessels cut down upon. The incision was placed so as to expose an inch or more of pulsating artery. Further novocain injections had to be made after incising the deep fascia, as the proximity of the great nerve trunks made the exposure of the artery painful at times. The axillary artery was seen to be pulsating freely, but it was not easy to be certain whether the pulsation felt was that of the normal vessel or merely transmitted. As a finger was passed downwards along the vessel a doughy substance was felt in its interior. This distal portion (brachial artery) was seen to be contracted, no larger than the normal radial, so that one passed from normal pulsating vessel, over a resistant portion to a contracted and apparently empty vessel. The artery was now freely encircled all round. This was difficult owing to the presence of the superior profunda artery, at the origin of which the embolism was situated. Clamps for occluding the

vessel were rapidly improvised by covering the serrated blades of artery forceps with appropriate rubber tubing. With these the vessel was gently held by my assistant, Mr. Galloway, and fulfilled their purpose admirably.

A longitudinal incision about 2 cm long was made into the vessel and a dark piece of clot immediately protruded. This was gently pulled out with forceps, and proved to be 2 cm long. The upper clamps were now momentarily released and blood rushed out, but no flow followed the release of the lower clamps. The vessel was therefore "milked" upwards, and a much larger piece of clot, rather whiter and more granular in appearance, was extruded. Blood was now seen to flow gently on release of the lower clamp. The wound in the artery was therefore sewn up with four fine silk stitches on a fine round bodied needle, the silk having been well soaked in liquid paraffin and the operation field drenched with the same fluid. The suture line was tested by release of the clamps and proved to be water tight. The clamps were then removed. The patient immediately said, "The pain is gone" and a few seconds later remarked that he could move his fingers and that the arm was becoming warmer. By the time the deep fascia and skin had been closed full function was restored to the arm, the radial pulse was full and free, the colour pinker than normal, and the grip strong. At first the pulsation in the left radial was not so strong as that in the right, no doubt because of the persistent main trunk constriction to which several writers have referred. In a few minutes it most it became stronger and remained so.

The relief afforded by this simple operation was dramatic in the extreme. From a condition of intense pain immediate respite was obtained. The use of local anaesthesia made it easy to corroborate objective recovery by the testimony of the patient himself, and there can be no doubt that this is the anaesthetic of choice for similar cases.

The arm made a perfect recovery without a suggestion of the most local gangrene, but on the fourth day after embolectomy he had a rigor and complained of intense pain in the right side of the chest. He was examined by my colleague Dr. Lingley, who found crepitations at the right base, where a pulmonary embolism had occurred. He found no evidence of cardiovascular disease or congenital abnormality. Blood appeared in the sputum shortly afterwards, thus confirming the diagnosis. The patient was much troubled by pain and coughing for the next week, but no further embolism occurred. A smooth convalescence followed, and he was discharged from hospital a month later.

I have recently (September 18th) had a further opportunity of examining him five months after the operation. His doctor informs me that two weeks after the man left hospital he developed a thrombosis of the left femoral vein which gave little trouble, but three weeks after that the right leg became thrombosed, and has continued swollen and painful until now, though he can get about on it. There are some enlarged venous radicles on the lower abdomen, which suggest that the thrombosis has extended perhaps as high as the inferior vena cava. His umbilical hernia and his arm remain in excellent condition. It should be remarked that his legs were frequently examined whilst he was in hospital for signs of thrombosis, but no abnormalities were at any time detected. Why he should have developed a thrombosis later is obscure.

Origin of the Embolus

The question of the origin of the embolus immediately arises. If he had some undiscovered thrombosis in the veins of the legs or pelvis (and his calves and thighs were never tender or swollen in hospital) the only route by which a portion of clot could have reached the axillary artery would be through a deficiency in the septum of the heart, for, of course, without such a means of short circuit a thrombus from the systemic or portal venous system must be filtered off by the lungs—the form of embolism with which we are more familiar. As a fact the patient did have a pulmonary embolism as well but we shall see that even that did not necessarily arise in a systemic vein. One naturally looks to the operation itself as furnishing the clot and it is a possibility that a "paradoxical embolism" occurred in the arterial tree through a patent foramen ovale. If such a deficiency were not present then the clot must have come from one of three places—from the pulmonary veins, from the chambers of the heart itself or from the intra or subclavian artery. How common is thrombosis in these sites? Fortunately we have some valuable information on that point. P. Bull has analysed 6140 necropsy records from the Ritz-Hospital at Oslo and finds that the heart has been greatly under-estimated as a source of clot for embolism. Thrombosis in the pulmonary veins was only found three

TABLE I—Embolectomy, 1922-1925

Case No	Author	Site of Embolism	Sex and Age	Cause	Duration of Signs of Arterial block before Operation	Result
1	Michaelsson (1922)	Left common femoral	M 53	Heart disease	23 hours	Amputation died ten days later
2		Bifurcation of aorta and right common iliac	F 58	Heart disease	11½	Died next day
3		Left common femoral	F 30	Heart disease	2½	Success
4	Haggstrom (1922)	Right iliac and femoral	F 41	—	16	Died next day
5		Right femoral and popliteal	F 52	—	10	Subsequent amputation, died six weeks later
6		Left iliac	F 69	Mitral stenosis	9½	Died next day
7	Senecart and Blum (1922)	Right axillary	M 53	Syphilitic aortitis	About 24 hours	Success
8	Buerger (1923)	Right brachial	M 57	Chronic endocarditis	6 hours	Died nine days later
9		Right brachial	—	Gangrenous appendicitis	3½	Success
10	Undberg (1924)	Left femoral and popliteal	F 62	Heart disease strangulated hernia	9½	Success
11	Michaelsson (1924)	Left common femoral	F 73	Aortic dissection	2½	Success
12	Perman (1924)	Left common iliac	M 46	Heart disease	3½	Success
13	Lundblad (1924)	Bifurcation of aorta	M 37	Heart disease	Next day	Died
14		Right common iliac	F 35	Heart disease paritum on two days previously	8 hours	Success
15		Bifurcation of aorta and the external iliac	F 47	Heart disease	26	Died
16	Olivecroft (1924)	Right common femoral	F 31	Mitral disease	2	Success (same patient as No 3)
17	Gejrot (1924) (operated on by Lange)	Right axillary	F 70	Arteriosclerosis	1½	Died seven days later
18	Torell (1925)	Left superficial femoral	F 32	Heart disease	23	Subsequent low amputation recovered
19		Right superficial femoral	F 22	Heart disease	5	Success
20		Left superficial and deep femoral	F 77	Heart disease	4½	Died five days later
21	Dickson (1925)	Right brachial	M 63	Uncertain	20	Subsequent amputation died thirteen days later
22	Henney Snyder and Horer (1925)	Left subclavian	F 62	Cholesterol	5	Success
23	Turettini and Gruder (1924) (operated on by Kummer)	Aortic bifurcation	F 19	Mitral disease	2	Died next day
24	Aleman (1925)	Common femoral	M 25	Heart disease	4	Success
25	Lundblad (1925)	Common iliac arteries	F 44	Heart disease	10	Success
26	Soderlund (1925)	Right popliteal	F 42	Heart disease	12	Success
27		Left brachial	F 45	Heart disease	5½	Success
28	Jefferson	Left axillo-brachial	M 42	After operation for umbilical hernia	2½	Success

times in this large series, and then only in conjunction with clotting in the heart. It was found nine times in the aorta, but only in the presence of severe atherosclerosis, and never in any other artery. But thrombi were common in the heart, occurring in 181 cases—67 times on the right, 63 times on the left, and 51 times on both sides. These facts explain the occurrence of embolism in both the systemic and pulmonary circulations, although the lungs are exposed to an additional danger of infarction by the frequency of pelvic and limb thrombosis in the post-operative period. It seems very probable, to put it no higher than that, that in the case just reported both emboli were derived from the heart. It will be noted in the classified list of published cases of embolectomy set out below how common cardiac disease has been as a cause of peripheral arterial block.

Diagnosis of Peripheral Embolism

There is no need to dwell at any length on the symptoms and signs of peripheral embolism. The sudden onset of intense pain in a limb, with loss of motor power, loss of sensation, pallor, marbling of the skin, subjective and objective coldness of the limb, and absence of pulsation in the chief arteries, form a sufficiently characteristic picture. The more difficult cases are those in which the obturation of the vessel is incomplete at first, becoming absolute later, either by secondary thrombosis or by the embolus slipping lower down into a narrower vessel. The embolus in these cases probably rides the spur at the bifurcation of a large artery or exit of a large branch. One has only to be on the look-out for embolism to make diagnosis certain within the first few hours. Early diagnosis is of paramount importance if operative treatment is to be of real service. It is interesting to notice the effects which Key's teaching

has produced in Sweden, for the practitioners are evidently sending their cases to the surgeon now the moment the relatively easy diagnosis has been made, with gratifying results. If left untreated the majority of peripheral embolisms end in amputation, usually at a high level. In one or two cases an incompletely successful operation has had the advantage of making amputation possible at a lower level than would otherwise have been necessary. The age of some of the patients (see Table I) may lead the practitioner to suspect senile gangrene rather than embolism. The sudden onset and the unilaterality of the symptoms and signs will usually make the diagnosis clear.

Technique of Operation

No special instruments are required. Novocain infiltration is the anæsthetic of choice. The incision of the vessel wall, removal of the clot, and suture of the outer coats follow the usual technique of blood-vessel surgery. Liquid paraffin or sodium citrate (1 per cent.) may be used to prevent premature clotting in the wound. The only important advance in technique over earlier methods may be that in cases of embolism at the aortic bifurcation a distal approach is better than a direct. In these exposure of both femorals, which are then lightly clamped and opened, is followed by retrograde catheterization, the clot broken up, and removed through the openings in both vessels. This method is likely to give better results than a transperitoneal operation in a patient who is probably a bad surgical risk, owing to the presence of the heart disease which has furnished the material for the arterial blockage. This method is not only one of absolute precision, but the condition of the patient may make it advisable, although much blood may be lost during the probing. Several cases are recorded in which the thrombus has slipped away when the artery was

exposed. A fresh incision should then be made lower down (for example over the popliteal vessels). Wounds in arteries are easily sown up, and one should not hesitate to make multiple incisions if occasion demands it.

The Time Factor

The only cases are those which do well, and this for very definite and precise reasons. The lodgment of a clot sets up two things which will in a few hours militate against a successful issue. These are first, endothelial changes which will cause a fresh thrombosis after the clot has been once removed, and secondly, a thrombosis slowly spreads from the original clot and may assume such dimensions as to make complete removal impossible. Within the first five or six hours these untoward effects are not likely to menace seriously the result, but after ten hours at least they become increasingly threatening so that at the end of twenty-four hours operation will usually be hopeless. It is probable that in the late successful cases already reported complete and absolute obstruction has not been present quite so long as would appear, or that a collateral circulation has in reality saved the limb. If surgery is to achieve a high percentage of successes it must be clearly understood that no cases (save perhaps haemorrhages) are more urgent than these. This lesson will be learned the more easily by reference to Table II, which I have made up from Key's collection (up to 1922), and those successes which have been published since.

TABLE II.—Time Factor. Twenty-eight Successful Embolotomies

Time	Key's Series	New Series (1922-25)	Totals
	Successes	Successes	
From 1 to 5 hours	5	10	15
From 6 to 10	4	2	6
From 11 to 15	2	1	3
From 16 to 20	1	1	2
From 21 to 24	1	1	2
Totals	13	15	28

For the sake of completeness the whole series of embolotomies which have been published since Key's paper so far as I have been able to find them are given in Table I. These new cases number 28, making, with Key's 45, a total of 73. The highest percentage of good results in the later series has been commented upon above, this improvement appears to have been due to earlier operation alone. Few of the cases abstracted in the table call for special comment. Only four operations undertaken within ten hours failed. In the nature of things a very high percentage of successes is unlikely ever to be attained, for emboli are apt to be multiple, and further infection elsewhere will sometimes carry off a patient in whom a local success has been won; moreover, the advanced age of the patient and the frequency of heart disease often make the subjects bad surgical risks.

Oliverson's case is especially deserving of comment as it bears special testimony to the value of embolotomies. A woman, aged 41, had suffered from valvular heart disease (mitral stenosis) for years. Pulmonary embolism had been observed on several occasions. In July, 1922, she was operated upon successfully by Michaelsson (Case 3 in Table I) for embolism of the left common femoral. In September, 1923, she suffered embolism of the right common femoral and again success was achieved (Oliverson, Case 16 in Table I). Six months later the patient was well and no evidences of disturbance of circulation in either leg could be detected. Soderlund's second case illustrates the old and the new methods (Case 27, Table I). A woman of 46 with chronic heart disease had an embolism of the right popliteal artery. No doctor was summoned for two days, gangrene supervened, and supracondylar amputation was performed. The patient was discharged well. Some months later embolism of the left brachial artery occurred. This

time she was sent into hospital immediately, where the embolus was removed, five and a half hours after lodging, with complete success. Two months later she was back at her work making paper flowers. These cases illustrate well the results which may at times be obtained, whilst they also remind us of the possibility or even probability of further embolism in heart cases.

A METHOD OF NASAL PLASTIC REPAIR BY CARTILAGE GRAFT

BY

E. WATSON-WILLIAMS, M.C., CH.M., F.R.C.S.D.,
CLINICAL LECTURER IN LARYNGOLOGY, UNIVERSITY OF BRISTOL

THE method here described has proved useful in the treatment of nasal deformities, especially those types where depression extends high up, when other measures have been unsatisfactory. A typical case best exemplifies the steps necessary.

A girl aged 15½ years was brought to me late in 1923 for the deformity indicated in Fig. 1. When 4 years of age she had had a blow which crushed the nose. No special treatment had been adopted. She had a most disfiguring depression of the middle and upper parts of the nose; the nasal bones appeared to have participated in the damage and there was marked obstruction

FIG. 1

FIG. 2

from the remains of the septum. The tip of the nose had suffered from atrophy of the septal cartilage and was sharp as well as being turned right up by the depression above. The first step was to secure a satisfactory framework by collecting the shreds of cartilage embedded in fibrous tissue which represented the remains of the septum and by freeing the adhesions which had formed between this and the sides of the nose (in front) and the turbinates (behind). When healing was complete this object had been attained but the appearance was hardly altered.

Four months later under general anaesthesia a graft of rib cartilage was inserted to raise the depressed portion. The rib cartilages had crept and formed the lower support of the graft, the upper end rested on the remains of the nasal bones.

Description of Operation

An incision is made in the skin, beginning at a point half-way along the lateral margin of one nostril running forward along the margin to the anterior end being carried

across the front of the columella transversely to the corresponding point on the opposite side, and down the lateral margin of the other nostril to finish opposite the starting point (Fig 3). From this incision, dissection is carried forward to the tip of the nose, raising the skin, and over the tip upwards. The skin here is tightly bound down to the nose, and sharp dissection is necessary until one arrives about half an inch above the tip. Thence a narrow tenotome is inserted under the skin as far as the glabella, the skin being raised by a narrow elevator, and by pinching up from outside. With the same knife, and also with a blunt-ended tenotome, the skin is freed on either side of this central passage, the width to which this is carried depends on the amount of depression, there must be no tension in the skin after the graft has been inserted, and any error in this step is likely to be a too springing rather than a too wide freeing (Fig 4). This part

FIG 3—Line of incision

FIG 4—Area of skin raised

of the dissection is easily accomplished, but special care is needed in passing from the sides of the nose on to the cheeks, where a region of firm attachment of the skin seems to be the rule. The progress of this, the most important part of the operation, can be watched from outside. During the dissection bleeding is apt to be free. The cavity can be inspected by means of Sir StClair Thomson's speculum or a narrow Killian speculum, inserted at right angles to the usual direction so as to open into the posteriorly. When a satisfactory cavity has been prepared it is packed to arrest bleeding. A piece of rib cartilage, somewhat larger than seems necessary, is now cut and shaped roughly. The packing is removed and the final fitting and trimming of the cartilage is carried out, the graft being tried in position to ensure accuracy. The tip of the nose, if formerly raised, will be found to be brought down appreciably by this manoeuvre, hence the reason for cutting the graft at first rather large.

In this case the graft was made to take a firm support on the nasal bones, a small notch on the under surface preventing any tendency to ride up. The lower end was brought down quite to the new tip of the nose and shaped to give a round tip. Three points of horsehair suture closed the incision. Firm pads were applied on either side of the nose to prevent lateral displacement during sleep, etc. but no dressing was used over the tip of the nose.

During the next day it was seen that extravasation of blood extended as far as the globular conjunctiva on either side the whole nose was oedematous especially over the formerly most depressed part. Convalescence was uneventful. A slight rise of temperature (to 99.4°) occurred on the second and third days but there was never any anxiety as to suppuration. The sutures were removed on the fourth day. The result six months after operation is seen in Fig 2. It is remarkable how the whole face improved but part of this may be due to relief of nasal obstruction and mouth breathing. The very slight scar cannot be seen if sought for except when the head is thrown back.

Some of the advantages of this method are:—The vessel is approached to the part avoids any mucous either by secondary operation may be regarded as aseptic lower down into a narrower vein the skin of the depressed cases probably rides the spur at artery or exit of a large branch extended as high as is the look-out for embolism to make full when treating high the first few hours. Early diagnosis. Importance of operative treatment is not down even below. It is interesting to notice the effects when even there rest

against an incision, if necessary, a second graft may be inserted in a channel in the columella, to raise a depressed tip.

5 The graft may be fitted and altered before closing the incision.

6 No scar is made on the front of the face.

On the other hand, the method is not quite so simple as some other procedures, it makes also a certain demand on the patience of the subject. But this last is almost inevitable when dealing with a considerable deformity—*il faut souffrir pour être belle!*

The remaining photographs are other examples of the method. Fig 5 shows a deformity from falling against a kerbstone seven years earlier, I have, unfortunately, no

FIG 5

FIG 6

record of the profile deformity, but the full face shows it well. Fig 6 is the same face in profile, after grafting, it shows how generously one may deal with a large nose. Fig 7 shows the result of sword cut, it is not quite a true profile, and the sharply angular deformity is minimized.

FIG 7

FIG 8

In this case the ability freely to separate the skin laterally was very valuable in dealing with the scar. The treatment of the interior of the nose had been a more difficult problem. Fig 8 shows the result.

Fig 9 shows a deformity arising from being knocked

FIG 9

FIG 10

down (and perhaps trodden on) by a cow when the patient was 3 years of age. It is given for contrast with Fig 10, taken six days after operation. The scar, below the tip of the nose, can just be seen, the marks on the tip are from blood-staining. The grain in intelligent appearance is well shown. (None of the photographs have been retouched.)

ULTRA-VIOLET LIGHT AND THE ANTI-SCORBUTIC VITAMIN

PHILIP EGGLETON, M Sc Lond,

AND

LESLIE J HARRIS, Ph D Cantab, M Sc Vict

The object of this communication is to present the experimental results obtained in a preliminary investigation, carried out in the autumn of 1924, to determine the relation, if any, of vitamin C to ultra-violet light. There are several grounds for supposing that there might be some such relationship. In particular, the fact that vitamin C is so largely associated with plant life suggests its possible intimate connexion with phyto-chemical synthesis. Vitamin C had not previously been studied from this aspect when this work was planned, although of course the relation of the antirachitic vitamin (the "D" fat-soluble factor) to light rays has claimed the attention of a number of investigators during the past year or two. Our conclusions, it may be confessed, have been mainly negative—namely, that the C vitamin does not show that interrelation with light which is apparent in the case of vitamin D, we are not at the moment continuing the work, but it is thought perhaps worth while to summarize our conclusions, particularly as other workers are now interested in this field.

HISTORICAL

The known facts relating to the fat soluble vitamins are briefly as follows (1) Coward¹ has shown that "light is necessary for the formation of vitamin A in plant tissues" (2) It is now well known also that the ill effects caused by insufficiency of fat-soluble vitamins can to some extent be remedied by exposing the animal on the deficient diet to a source of ultra-violet light.^{2,3} (3) Finally, it has been shown by Steenbock and his collaborators,⁴ and independently by Hess,⁵ that it is possible to revert a ration deficient in fat-soluble vitamins by exposing it to light, thereby conferring upon it both growth-promoting and calcifying properties, cholesterol has recently been activated in this way.⁶

Light appears to have no effect upon vitamin B phenomena.

FIG 1—Effect of light on synthesis of vitamin C in germinating oats. Average growth of guinea pigs fed on—A oat ungerminated C oat only E oats only germinated in daylight. All animals received in addition daily rations of cod liver oil (1 drop) brain rock salt and water. The amount of food eaten was weighed daily (same applies to all figures).

EXPERIMENTAL

Our investigations were concerned mainly with the effect of mercury vapour or other light on

- 1 Synthesis of vitamin C in the plant
- 2 Animals kept on a scorbutic diet (attempt at prevention)
- 3 Animals already with scurvy (attempt at cure)
- 4 Rations with partly destroyed vitamin C (attempt to regenerate)
- 5 Rations rich in vitamin C (attempt to augment)

* The view (proved erroneous in this paper) that "ultraviolet light" is necessary for the synthesis of vitamin C has been taken for granted in some quarters without any scientific evidence. According to Luce and Maclean, however, yeast cells can synthesize vitamin A in the absence of sunlight.

Throughout we used a Cooper Hewitt quartz mercury vapour lamp. The power of the lamp to emit ultra-violet rays was tested by means of Webster, Hill, and Edinow's acetone methylene blue solution.¹⁰ No special precautions were taken to prevent oxidation of exposed foodstuffs. It is unlikely that our main conclusions would be affected if oxidation were to be rigorously excluded.

FIG 2—Relative efficiency of oats germinating in light or dark in preventing scurvy. The above are average growth curves for sets of three or more animals. All animals consumed the same weight of germinated oats (calculated in weight of original ungerminated cereal) whether germinated in the dark in light from the mercury vapour lamp, or in daylight. Oats germinated in the dark had sprouted most and were most efficient in preventing scurvy. In the experiment here represented germinated oats were approximately 50 per cent of the total food consumed. Other details as in Fig 1.

1 Synthesis of Vitamin C in the Plant

Ungerminated oats contain no vitamin C. During germination vitamin C is known to be synthesized. We carried out tests to determine whether light was necessary for this synthesis, we found it was not necessary. The diagram (Fig 1) needs no further explanation.

Relative amounts of Vitamin C Produced in Dark and in Light Respectively—Incidentally it was observed during the course of this part of our investigations that oats, germinating in the dark and producing therefore a greater

FIG 3—Effect of exposing animals on scorbutic diet to mercury vapour lamp. Broken line= scorbutic controls in dark (diet completely deficient in vitamin C). Continuous line=animal on same diet but exposed to mercury vapour lamp (few minutes to several hours daily distance from lamp averaged about 4 feet). Normal controls were also taken (not shown in chart).

length of shoot than when exposed to the light for the same length of time and under the same conditions, produce a correspondingly greater amount of vitamin C. In other words, a larger ration is required of oats germinated in light than of oats germinated in the dark, in order to prevent scurvy. This is illustrated in Fig 2.

2 Effect of Light on Animals on a Scorbutic Diet

We found that guinea pigs exposed to daylight, to mercury vapour light, or to very dull light (diffused from filament lamps) all developed scurvy equally and after the same period when fed on the same completely scorbutic diet (Fig 3). Experiments upon the effect of irradiating

on a diet only partly deficient in the anti-scurvy vitamin are still in progress

3 Effect of Light on Recovery from Scurvy

We found that animals recovered from scurvy at apparently the same rate whether exposed to the mercury vapour lamp or not, when fed on the same curative diet (Fig 4)

FIG 4—Effect of exposing to light of mercury vapour lamp animals recovering from scurvy. The amount of vitamin C supplied during recovery was strictly limited (24 grams of cabbage per animal in all cases, 1 gram being approximately the minimum to prevent scurvy) so that any curative action of the light might be better detected. Continuous line—animals irradiated during recovery only. Broken line—non irradiated controls. Preparatory (scurvy producing) diet was of oats, bran, cod liver oil, rock salt and water.

4 Effect of Light on Rations in which Vitamin C had been Partly Destroyed

In our earlier experiments we thought we could observe a partial regeneration of vitamin C in heated cabbage after exposure to the mercury vapour lamp. The effect, however, was so slight—a possible delay in the appearance of scurvy for a day or two—that we attach no significance to it.

The following chart (Fig 5) summarizes a typical experiment, in which exposure of previously heated cabbage to mercury vapour light was without apparent effect on its antiscorbutic potency.

FIG 5—Animals received in addition to scorbutic diet (bran, oats, rock salt, cod liver oil, water). Animals A, 5 grams raw cabbage; animals B, 5 grams raw cabbage heated to 100° C for 1 hour; animals C, 5 grams raw cabbage heated to 100° C for 1 hour and subsequently exposed to mercury vapour lamp (at a distance of a few feet for varying periods up to 4 hours per diem).

5 Effect of Mercury Vapour Light on a Ration Rich in Vitamin C

We exposed to the light of a quartz mercury vapour lamp rations rich in vitamin C (for example, a proprietary infants' food), and compared their antiscorbutic value with that of the same unexposed foods. We were unsuccessful in finding any augmented antiscorbutic value. (See Fig 6)

Absence of Secondary Radiation Effect

The fact that vitamin C has its main source in the vegetable kingdom raises the question whether there is

any direct connexion between it and radiant energy in the form of light rays. For fat-soluble vitamin such a connexion is known to exist, and some would go further—basing then arguments on the protection against A or D avitaminosis conferred upon animals (a) by direct exposure to ultra-violet rays, or (b) by contact with other

FIG 6—Effect of ultra violet light on antiscorbutic value of food stuff rich in vitamin C was mixed with the standard scorbutic diet so as to supply only 60 per cent of the minimum required to prevent scurvy in guinea pigs. No delay in onset or modification of the symptoms was found in parallel feeding tests where the foodstuff had been exposed to ultra violet light immediately prior to feeding. Continuous line—guinea pigs on irradiated diet. Broken line—guinea pigs on control (non irradiated) diet. Normal controls were also taken (complete diet).

animals which have been exposed (it is claimed),⁹ or (c) by consumption of dead food or growing plant which has been irradiated, or (d) by dwellings previously irradiated (disputed)¹⁰—and would maintain that in the prevention of avitaminosis some form of radiant energy plays its part no less than a definite chemical substance, the accessory food factor. There is little or no experimental evidence to support this contention. Our previous results make it highly improbable that the C factor is interrelated with radiation phenomena. The following experiment, yielding, as was expected, negative results, is in further agreement with this view.

We allowed ultra-violet light from the quartz mercury vapour lamp to act on various foodstuffs, some rich and some deficient in the C factor, and tested these foodstuffs immediately afterwards towards a photographic plate. No activity towards the plate was found.

It may be noted that Dr Janet Clark¹¹ has recently arrived at a conclusion similar to that reached by us in our second section. Honeywell and Steenbock¹² have separately investigated a problem similar to that dealt with in our first section and reached a similar conclusion. They used germinating barley, while we used germinating oats.

DISCUSSION ON INFANTILE SCURVY

The statement that the synthesis of vitamin C in the plant is dependent upon the action of sunlight has appeared in more than one textbook, but no experimental evidence has been produced in support of it. True, it has been urged in this connexion that infantile scurvy is (according to clinical observation) more prevalent after the darkness of winter than in summer. The explanation, however, may well be—quite apart from all questions of greater susceptibility to disease during winter conditions—that bottled infants* receive in winter milk less rich in vitamin C than in summer, owing to the fact that the cow's winter diet is relatively deficient in fresh greenstuff or other sources of vitamin C. The antiscorbutic value of milk has been shown to depend on the presence of the C factor in the

* The disease is rarely encountered in breast fed infants for the human mother's winter diet is not so seriously restricted as the cow's although such sources of vitamin C as salads and fruits are scarce in winter. Oranges and potatoes are in most cases readily obtainable and cheap. Further breast milk is received by the infant with its vitamin value unimpaired, while bottle milk may have had its value diminished by pasteurization, boiling, or drying.

dict Cow's milk is accordingly richest in this vitamin when the animals are at grass*. The lower antiscorbutic value of winter milk may therefore be attributed to the cow being put on an inferior dietary, rather than to any direct action of sunlight on the diet (or on the animal itself).

CONCLUSIONS

A noteworthy antithesis is seen to exist between the fat-soluble vitamins and the antiscorbutic vitamin. The antiscorbutic vitamin can be synthesized in complete darkness, and experiment has so far failed to connect it in any particular whatever with ultra-violet light, the fat-soluble vitamins, on the other hand, have been shown to be affected by ultra-violet light in their synthesis and activation as well as in the prevention and cure of vitaminosis. The apparent independence of vitamin C to light is in a sense surprising, in view of its special association with the plant, in the metabolism of which light plays so important a part.

The practical significance of our results is to emphasize the importance of the provision of the C factor in diets. While it is possible to replace the fat-soluble factors to some extent by light rays (acting either on the diet or the animal), the prevention of scurvy must—in the present state of knowledge—rest upon the provision of adequate supplies of vitamin C in the food. Of special interest is this in relation to infantile scurvy—Barlow's disease. It is worthy of note that of the numerous proprietary foods sold as substitutes for maternal feeding, we know of only a single one that can claim to contain in itself an adequate supply of the antiscorbutic factor, permitting one to dispense with food adjuncts.

SUMMARY

The association of vitamin C with plant life suggests its possible connexion with phyto-chemical synthesis. Yet,

- (1) Light was found not necessary for the synthesis of this vitamin (in germinating grain), contrary to former supposition and in distinction to vitamin A, which is said to require light for its formation in the plant,
- (2) The direct exposure of an animal on a scorbutic diet to ultra-violet light did not appreciably retard the onset of scurvy,
- (3) Ultra-violet light appeared to have no curative action on a scorbutic animal,
- (4) Cabbage in which the C vitamin had been largely destroyed by heat was exposed to the mercury vapour lamp and tested for regeneration of the vitamin, with doubtful results,
- (5) Exposure to ultra violet light of an infants' food already rich in vitamin C gave no evidence of an augmented antiscorbutic value.

These results indicate that while the effects of fat-soluble vitamin deficiency in, for example, an infant's diet can be remedied to some extent by exposing the infant (or the food) to sunlight, if one is to prevent scurvy one must rely on an adequate amount of vitamin C in the diet.

Cow's milk may be deficient in this vitamin in winter owing to the animal's inadequate stall diet. The observed increase of infantile scurvy in late winter probably results from this cause rather than from absence of sunlight, to which it has been attributed latterly without sufficient evidence.

We wish to express our cordial thanks to Professor Sir F G Hopkins, F R S, and Professor J C Drummond for much kind interest and encouragement.

CYSTIC DILATATION OF THE COMMON BILE DUCT

BY

NORMAN H HILL, M D LOND, M R C P,
ASSISTANT PHYSICIAN, BELGRAVE HOSPITAL FOR CHILDREN

AND

R A RAMSAY, M CHIR CANTAB, F R C S,
ASSISTANT SURGEON, BELGRAVE HOSPITAL FOR CHILDREN

THE following case is of interest owing to the rarity of the condition, the difficulty of making a correct diagnosis, and the pathology of this and somewhat similar conditions.

H F, female, aged 2 years and 3 months was admitted to the Belgrave Hospital for Children on January 2nd 1925. The child had been vomiting for a fortnight and a rapidly progressing enlargement of the abdomen had been noticed for the past month. The vomiting started with occasional attacks, and she vomited about four times during the first week. This became worse and during the week prior to admission she vomited every day, and sometimes three times a day. The vomit was independent of food and was chiefly nocturnal. She did not complain of any abdominal pain, and was not constipated.

She was said to have had an attack of jaundice when 9 months of age, which lasted for some weeks, but had had no other illness. She was breastfed for eight months and then given glaxo and cow's milk. She was the youngest of a family of five. Three sisters and one brother were alive and well, one sister, the fourth child, aged 4 years, had jaundice at 2½ years, which lasted four months, but is now healthy and the abdomen normal to palpation, the jaundice having apparently been of a catarrhal nature.

On admission the temperature was 97°, the pulse 116 and respirations 24. The child was fairly well nourished, there was no jaundice, but the complexion was of a rather "earthy" hue. The tongue was moist and covered with a thick white fur. The cranial nerves, heart and lungs were normal. The abdomen was large and protuberant, and the percussion note was tympanic all over, including the flanks. The liver could be felt two fingerbreadths below the costal margin, its edge was sharp and very hard, it was not tender. The spleen also could be felt about two fingerbreadths below the costal margin. On the right side of the abdomen a large mass extended from beneath the liver to just above the crest of the ilium. It did not appear to move on respiration. On bimanual examination the tumour was found to extend backwards into the right loin. It was thought to be a tensely cystic swelling in connexion with the right kidney, but owing to the distension of the abdomen it was difficult to palpate. It was not tender. The urine was faintly alkaline, and contained no albumin, sugar, or bile salts or pigments.

During the first week the child vomited nine times. She was not constipated, and the faeces were of a normal colour. She lost weight. A blood count showed red blood cells 5,095,000, white blood cells 7,200, haemoglobin 90 per cent, colour index 0.88. The various cells were in their normal proportions. The Wassermann reaction was negative. The vomiting which occurred mostly at night, improved with alkalis, and during the second week three small vomits only were recorded. They consisted of partially digested food and a small quantity of bile-stained fluid. During this week weight was regained and became the same as on admission.

During this period in hospital the temperature, pulse and respiration remained normal, but the abdomen was still very distended and the swelling in the loin was thought to have increased in size. In spite of the facts that the vomiting had stopped that she took her food fairly well, although never very hungry, and that the bowels were open she began again to lose weight and it was decided to perform an exploratory laparotomy in order to ascertain the nature of the tumour.

Operation

On January 19th one of us (R. A. R.) opened the abdomen under general anaesthesia by an incision through the right rectus muscle over the tumour. The tumour was found to be globular and cystic and about four inches in diameter. It lay below and separate from the liver, the right kidney was clearly felt behind the cyst, and the duodenum lay upon and was closely adherent to its anterior surface. The liver felt hard and its surface rough and the gall bladder slightly distended projected between the liver and the cyst. The cyst was explored with a needle and syringe, and clear mucoid pale yellow fluid was withdrawn. The cyst was sutured to the margins of the upper part of the abdominal wound, and a tube inserted into its cavity through a small incision, to the edge of which it was fixed by a stitch. Leakage was prevented by a purse-string suture inverting the edges of the incision in the cyst around the tube. The abdominal wound was closed except for the point at the upper part where the tube emerged.

Examination of the fluid aspirated from the cyst showed that it contained no albumin, no urea and no pancreatic ferments. It contained bile salts and bile pigments.

After History

The day following the operation the child seemed fairly well, there was no vomiting, the bowels were not open, but a small pale motion was passed the day following (January 21st), and on January 22nd two stools of normal colour and consistency. After this the stools were extremely pale and contained no bile salts or bile pigment. The wound drained profusely, some days more than others and in amounts varying from 10 to 20 ounces of thin greenish yellow bile.

Death

general condition of the child meanwhile became steadily worse and at no time after the operation was she in a fit state to attempt further operative measures. There was no vomiting and no special symptoms, the child simply became weaker and weaker. Bile in various forms by the mouth was tried, and also reduction of fats in the diet, but no improvement took place. She went steadily downhill and died on February 10th. During the post-operative period the wound remained clean and the temperature and pulse were not raised.

Post mortem examination revealed a cystic swelling situated in front of the right kidney and behind the second part of the duodenum which it had pushed forward. The swelling also extended behind the head and the greater part of the body of the pancreas. When injected with formalin to preserve it it held 140 ccm. and would probably have taken 20 to 40 ccm. more. On dissection this swelling was found to consist of a cystic dilatation of the common bile duct, continued into the hepatic ducts and also into the cystic duct where it joined the common bile duct. The walls of the cyst were about 2 mm. thick.

The whole of the extraduodenal portion of the common bile duct was involved in this cystic dilatation, and it was so closely adherent to the duodenum that no duct could be found between the cyst and the duodenum. The opening from the cyst into the duodenum consisted of a small slit-like orifice at the lower end of the cyst. There was no flap of mucous membrane guarding it. After the specimen had been hardened in formalin, the patency of this orifice could not be demonstrated, but the opening into the duodenum appeared to have been very oblique. The pancreatic duct was patent and appeared normal. The gall bladder was collapsed. The liver was enlarged, hard and definitely cirrhotic. The spleen was also enlarged and presented rather a mottled appearance.

Microscopical Examination—The cyst wall was composed mainly of dense fibrous tissue. The inner layer was not quite so compact, and in places flattened epithelial cells could be recognized.

The liver showed a coarse cirrhosis of portal distribution, the fibrous tissue in the portal spaces was well formed and contained bile ducts, the larger of which were dilated and all of which had thickened walls. The bile ducts were lined with normal epithelium. The smaller ducts were more numerous than usual though no actual proliferation was seen. The cirrhotic condition did not spread along the smaller bile capillaries nor between the liver cells, though here and there detached liver cells were seen in the fibroid area.

The spleen pulp was intersected by strands of fibrous tissue, many of which appeared to have been formed by thickening of the normal trabeculae of the organ. In close relation to them the larger blood vessels lay, and from them more delicate strands of fibrous tissue spread into the spleen pulp. The blood sinuses of the spleen were moderately distended. The Malpighian corpuscles were of normal appearance.

Nearly fifty cases similar to the one described have been recorded and possibly more might be included, as many observers have omitted doubtful or insufficiently described cases.

McWhorter,¹ in his excellent and comprehensive survey of the literature, states that cases in which there was a definite pathological condition explaining any obstruction, such as congenital atresia, pancreatitis, stone, or inflammatory stricture, were not included in his series, yet in his own case he describes the one as containing some "hidradenoma-like" stones, and the hepatic ducts as being partially filled with similar stones. He has, for instance, excluded Milner's case, without, it seems to us, sufficient justification.

The condition is looked on by most observers as congenital, the evidence being that Heiliger² described a similar condition in an almost mature foetus, and from the fact that most of the cases recorded have occurred in children and young subjects. The average age for the onset of symptoms would appear to be between 10 and 14 years. 12 to 14 in Walker's³ series, and rather younger in McWhorter's. Of the cases recorded 87 per cent. occurred in females.

In all the recorded cases there has been evidence of obstruction to the outflow of bile from the common duct into the duodenum. This has been shown

1. *Clinically*, by the symptoms of jaundice, which has occurred in all but three cases, the jaundice either having been present at the time the patient came under observation or a history of one or more attacks elicited.

2. *Pathologically*, by the fact that in many cases no opening from the common duct has been found at operation or autopsy, although from the patient's history an opening must have been present either at the time or very shortly before. In other cases where an opening has been found, obstruction has been demonstrated by oblique openings, valve-like folds of mucous membrane, etc.

3. *From Post-operative Recovery*—Cases in which a primary choledcho-duodenostomy has been performed have

recovered, in other words, the obstruction has been overcome by means of a short-circuit.

In cases examined *post mortem*, some observers describe a fold of mucous membrane overhanging the distal end of the common bile duct, and preventing bile from reaching the duodenum until the sac (upper portion of the bile duct) has sufficiently dilated to expose the opening. Others describe an abnormally oblique entry of the bile duct into the duodenum. Others, again, suggest that the cause of obstruction may be of the nature of an inflammatory duodenitis involving the duodenal portion of the common bile duct. Together with this obstruction it is assumed that there is a congenital weakness of the walls of the bile duct in its upper part, the cystic dilatation of the duct only involving the extraduodenal portion, and often only the upper two-thirds of the common bile duct.

It seems clear, therefore, that in all recorded cases there has been obstruction to the outflow of bile, that the obstruction is partial and intermittent, that the obstruction tends to progress—all cases not operated upon having died. While most observers take it for granted that the cyst is congenital, does it not seem far more likely that the obstruction is the congenital anomaly, and the cystic dilatation merely secondary to this, comparable to a hydronephrosis produced by chronic partial obstruction to the urinary outflow?

In no case has a diagnosis of this condition been made before operation or autopsy. This is hardly surprising since so few cases have been recorded. In nearly every case the surgeon has been unfamiliar with the condition.

In almost all the cases the symptoms have been similar, consisting of attacks of jaundice, abdominal pain, progressive enlargement of the abdomen, and a cystic swelling on the right side of the abdomen. The swelling has been variously diagnosed as a hydatid cyst of the liver, hydro-nephrosis, ovarian cyst, etc. The enlargement of the liver and spleen, such as occurred in our case, is by no means universal, although it occurred in Milner's case with very similar *post-mortem* findings. In some cases a biliary cirrhosis of the liver has been described. As regards treatment, where the cyst has been extirpated, its nature not having been realized at the time of operation, the mortality has been 100 per cent. The cases treated by drainage of the cyst alone have, with one or two exceptions, died. In some of these a subsequent choledcho-duodenostomy has been performed with success, but in most cases where it has been attempted it has failed.

The operation of choice is choledcho-duodenostomy at the first operation so as to provide internal drainage of the bile into the duodenum. From the position of the cyst, which lies just behind the duodenum, this should not prove too difficult an operation, provided the patient is not very young and is in good condition. The ease or difficulty of the operation may be determined in part by the thickness of the cyst wall, as in some cases it is quite a substantial structure, while in others it is so delicate that it has actually ruptured at the time of operation.

For a complete bibliography of the condition the reader is referred to the papers of McWhorter and Erik Waller, previously quoted.

We are indebted to Dr. T. H. G. Shore for the preparation and description of histological specimens.

TREATMENT OF HAEMORRHOIDS BY THE GALVANO-CAUTERY

BY

W. S. WHITCOMBE, M.D.

THE objections to the ordinary surgical methods for the cure of haemorrhoids are considerable. Among these are the damage to normal tissue, the raw surfaces left and consequent exposure to faecal infection, the lengthened process of the healing of the sloughing mucosa, the prevalence of pelvic encephaloma, the loss of time and interference with occupation, the ordeal of an operation with

its very trying after-effects, the expense of the anaesthetist and nursing home charges, etc.

The method of treatment by injections of a solution of carbolic acid 10 per cent in water and glycerin—or, as preferred in America, of quinine and urea—has been in use for many years, and has probably been tried by most of us. Unfortunately it is suitable only in simple uncomplicated cases and fails in some 50 per cent, moreover, it sometimes causes very severe pain, lasting many hours, even in experienced hands.

Treatment with the galvanocautery is almost as simple, is successful in every class of case, is painless, entirely under control, leaves no raw surface, can be performed on the consulting room couch at a moment's notice, occupies only a few minutes, and does not necessitate lying up or interfere with occupation. I have used this method for over twenty years and have never seen a failure, complication, or recurrence.

The patient, who is advised to come with an empty bowel, lies on the left side with a square of waterproof material tucked under the buttock and a packing of cotton wool to catch any bleeding. The anus is first dealt with the effort of the patient, with the rubber clad finger, brought down with the rubber clad finger. Messrs Allen and Hanburys have modified the one used by the late Mr. Graeme Anderson, lipped and partially cut away at the upper end. Mine has the advantage that it will revolve, allowing any portion of the interior of the bowel wall to drop into the cut away opening without moving the handle from the posterior buttock groove, two small eyelets to attach hooks from a waist belt make the speculum self retaining.

The mucosa is swabbed with a solution of crystal violet and brilliant green (1/500 of each), or of acriflavine (1 in 500). Eight minims of a sterile local anaesthetic, such as 2 per cent novocain with adrenin and two drops of a 5 per cent solution of carbolic acid added in a minim measure glass, are injected into the submucous cellular tissue at the base of the pile. I prefer the genuine Record syringe, using an adapter with Schummel needles, these are so fine that the puncture closes at once. A minute later the pile is punctured to the depth of from one quarter to one third of an inch with a bulb pointed burner (made for me by Messrs. Allen and Hanburys), not platinum, but an iron alloy which does not bend easily when hot and has a higher caloric capacity. A small pile needs only one such puncture, a large one perhaps three or four, especially if it is tough and fibrotic. The cautery bulb point must go into the vein and be kept there, moving it in and out to prevent it sticking, until the blood is coagulated and bleeding stops. I never treat more than two piles at one sitting.

The local anaesthetic gives confidence, and I use it because, also, I have many times noticed patients flinch a little during the burning. It is advisable to blow away gently any steam or smoke which shows itself.

The speculum is then withdrawn, the interior of the bowel is lubricated (I prefer the old gall and opium ointment), and the pile mass pushed up through the sphincters. A good sized piece of cotton wool is wedged over the anus, into the buttock fold, and the patient can go back to his occupation, perfectly comfortable. He should return in a week. By that time there will be little or nothing to feel of the pile or piles so treated, and more can be done. The patient will say that, beyond a little bleeding after a motion, or a little sanious discharge, he has had no discomfort. Piles so treated rarely come down afterwards, and no slough is noticeable. The flaccid and loosened mucosa is fixed back by the cicatricial contraction which takes place and gradually shrinks all round, the sphincters regain tone and shut with a snap as they should do.

The small nodular, very painful swelling which appears suddenly during strain at the anal orifice and distresses so many of us in active life is for convenience called a pile, but it is not of the nature of the looped varicose vein which constitutes the ordinary haemorrhoid. It is a clot due to the accidental rupture of a small vessel into the subcutaneous connective tissue. It cannot be replaced, whereas the ordinary submucous pile is not painful and can be pushed back. The cautery is useless in this case. The clot can be cleared out through a half-inch incision into the skin, under infiltration anaesthesia, this gives immediate relief, and if the cavity be swabbed out with flauine the cut heals by first intention. If the cavity has previously become septic it must, of course, be drained. The alternative is rest in bed, a hypodermic injection of morphine, and hot fomentations.

SIR BERKELEY MOYNIBAN, Bt, KCMG, CB, MS,
FRCS, President

DISCUSSION ON ACUTE INTESTINAL OBSTRUCTION

OPENING PAPERS

I—SIR WILLIAM TAYLOR, KBE, CB, MD, LL.D.,
Regius Professor of Surgery, Dublin University

THE TREATMENT OF PRIMARY ACUTE INTESTINAL OBSTRUCTION

THE surgery of the acute abdomen has advanced so satisfactorily during the past twenty-five years for every condition, with the sole exception of acute intestinal obstruction, that one is compelled to ask why the mortality attending the treatment of this condition should be not one whit better to day than it was at the beginning of the century. The reason for this appalling state of affairs is not difficult to discern.

It is solely due to what, in truth, may be described as the ignorance and carelessness, both of which are inexcusable and are indeed nothing short of criminal, of the general practitioners or physicians who see these unfortunate cases in the earlier stages of their illness. Instead of recognizing that purgation and enemata can do no good, but, on the other hand, may do an infinity of harm, apart from the delay in surgical treatment their administration produces, these practitioners are continually laying themselves open to an action at law for malpractice, or, worse still, they run the risk of being placed in the dock and charged with manslaughter.

If the truth were generally known, the mortality attending the surgical treatment of primary acute intestinal obstruction the result of intra-abdominal conditions is nearer to 60 per cent than the 35 to 40 per cent usually stated—a truly shocking state of affairs. I may say that I almost get a rigor when I receive a telephonic message to ask me to go to hospital, either public or private, to operate upon a case of acute intestinal obstruction. Physicians and general practitioners have all come to recognize that the only satisfactory treatment for all other acute intra-abdominal conditions is early surgical intervention, but why they cannot be got to come to the same conclusion with regard to the treatment of acute intestinal obstruction passes my comprehension.

For over twenty years I have been accustomed to teach that apart from acute intussusception, three stages can be recognized in these cases, and that the treatment must necessarily vary according to the stage in which one finds the patient.

The first stage is that in which the patient is seen early (within twenty-four hours). His general condition is good and there is but little intestinal distension. The second stage is that in which the patient is not seen until later—two, three, or four days. His general condition is good, but there is considerable intestinal distension and severe vomiting which may or may not be stercoraceous. The third stage is that in which the general condition of the patient is bad. His pulse is feeble and perhaps intermittent and vomiting is almost continuous and is certainly stercoraceous. The abdomen is greatly distended, and the patient presents the appearance of one profoundly poisoned by the absorption of toxins, whether the result of bacterial activity, or a proteose intoxication, or a combination of both conditions.

The treatment of the first stage consists in washing out the stomach with sodium bicarbonate solution. A general anesthetic is administered and the abdomen is freely opened. The cause of the obstruction is searched for and removed, after which the abdomen is closed. The stomach is again washed out and the patient returned to bed. Lavage of the stomach after operation is more important, in many cases, than it is before the operation.

In the second stage a similar procedure is adopted until the obstruction is discovered and removed. A separate incision should then be made through the left rectus muscle above the umbilicus, and a loop of the jejunum, as close to its origin as possible, is brought out through the wound. Into it is fastened a tube of 7 or 8 mm diameter, after the method of Senn's gastrostomy, except that only one or two purse string sutures are used, so that too much subsequent narrowing of the intestinal lumen may be avoided. The intestine is then returned within the abdomen and fixed with two catgut sutures, one on each side of the tube, to the parietal peritoneum and posterior sheath of the rectus. A lunated piece is cut out of each side of the end of the tube before it is introduced into the intestinal opening, so that if it should accidentally impinge upon the opposite wall of the bowel the intestinal contents could still escape freely. By this procedure the distended intestines will be allowed to empty themselves of their poisonous contents. The central wound is then closed. The stomach is thoroughly irrigated as before, and the patient put back into bed. An experienced nurse or a senior student is directed to continue irrigating the intestines with sodium bicarbonate solution by siphonage through the tube. In this way, without taxing the patient's strength and without producing any shock, the intestines are assisted to empty themselves. This process can be continued for several hours, at the end of which time the entire intestinal area between the stomach into which the tube has been introduced and the point at which the obstruction existed will have been emptied of its contents, and these contents replaced in large measure by a fluid containing sodium bicarbonate and glucose, the absorption of which will counteract the tendency to acidosis and help to build up the reserve carbohydrates as well as replace the fluids of which the tissues have been deprived by the continuous vomiting.

I have been so impressed by the soundness of the teaching and importance of the views of Mr Victor Bonney, as recorded in the *Middlesex Hospital Reports* and the *BRITISH MEDICAL JOURNAL*, that I have discarded all other methods of emptying the distended intestines of their poisonous contents and have followed the procedure outlined above. In the majority of these cases the tube can be removed in twenty-four or forty-eight hours under gas or local anesthetic. A single mattress suture will close the intestine. If Dr C H Mayo's suggestion of bringing the tube out through a hole in the great omentum is adopted, the necessity for a suture to close the opening into the intestine after removal of the tube will be obviated. Lactose may be given freely either by mouth or through the intestinal tube, as it has been shown that lactose can eliminate proteolytic bacteria from the intestinal flora.

In the third stage the patient is too ill to stand the administration of a general anesthetic, and he is not even removed from the bed in which he lies. The stomach is washed out as described above, after which the tissues of the abdominal wall above the umbilicus are infiltrated with a 1/2 per cent solution of novocain. An incision of 1 1/2 or 2 inches is then made through the middle line or left rectus muscle, as may be desired, into the abdomen. A finger is introduced and a loop of the jejunum, as near to its origin as possible, is withdrawn. A tube is then introduced into this fluid-containing segment of gut as before described, and siphonage similarly continued.

Should the patient survive, it may be possible at the end of a week to open the abdomen, seek out the cause of the obstruction and remove it. In the meantime nourishment can be administered through the tube directly the intestinal contents have been evacuated, or it may be given by mouth. The tube must not be removed until the

patient has recovered from the effects of the second operation.

I am convinced that in all cases of intestinal obstruction in which stercoraceous vomiting has occurred, drainage of the jejunum as close to its origin as possible should be instituted. This drainage can be assisted by repeatedly filling up with sodium bicarbonate solution and siphoning off the intestinal contents after the patient has been returned to bed.

In a paper by Dr Czar C Johnston of Lincoln, U.S., on the treatment of adynamic ileus, published in the *Nebraska State Medical Journal* in 1920, an almost identical procedure to that I have described for the treatment of patients in the third stage of acute intestinal obstruction is advocated. As has been pointed out by Dr J E Summers of Omaha, Nebraska, Bonney's method of performing a jejunostomy is the one flaw in his otherwise sound paper.

The treatment of acute obstruction engrafted upon chronic is somewhat different. The site of the chronic obstruction will almost invariably be found to be somewhere in the large intestine, and in all such cases the bowel above the obstruction should be drained at once. A caecostomy after the method of Sir Harold Stiles gives the best results so far as tiding the patient over his immediate dangers is concerned. This carries out Bonney's idea of draining the fluid-containing segment.

Of the various mechanical conditions producing primary acute intestinal obstruction within the abdomen intussusception has been by far the commonest I have myself encountered. There is no acute abdominal condition more easy to diagnose, and that, too, although the majority of such cases we met with in young infants who are unable to speak. There cannot be any excuse for failure to recognize this condition within from an hour or two to twelve hours after its onset. The condition is met with most frequently in infants between the ages of 2 1/2 months and 10 or 12 months—my youngest case occurred in an infant of 2 1/2 months. It is occasionally met with (but with diminishing frequency) at all ages up to 70 or more. My oldest case occurred in a woman of 73 years. The evidences in an infant are so typical that one has only to see one case, or hear the phenomena described, in order to be able to make a correct diagnosis—and that, too, within a few hours after the onset.

The diagnosis of intussusception once made, the only satisfactory method of treatment consists in early operation, and reduction by gentle expression from below upwards. Care should be taken to see that the least dimple at the site of commencement of the intussusception is expressed. I have not seen any case recur after operation. My own mortality has been 3 deaths in 81 cases. In two of these cases resection had to be performed, while the third death took place from convulsions on the tenth day after operation, when the abdominal wound was soundly healed, and the child was considered fit to be taken home. For some years past I have sent these cases home a few hours after they have recovered from the effects of the anesthetic. The mother reports daily to the hospital as to the infant's progress or a student visits the case and reports to me.

I believe that this condition is one which requires greater gentleness in manipulation and greater rapidity in operating, if success is to be uniformly attained, than almost any other intra-abdominal trouble. Given an average case of less than twenty-four hours' duration, I think the completed operation should not require more than ten or eleven minutes to perform. Early diagnosis and early operative intervention will reduce the mortality from the figure at which it is generally recognized to stand to-day to less than 5 per cent.

With regard to the treatment of acute intestinal obstruction of the adynamic type, Mr Sampson Handley's method and advocacy leave little to be said on the subject. I would merely suggest, with all due deference, that in bad cases drainage of the jejunum high up and siphonage of the intestines plus lavage of the stomach, combined with morphine, will sometimes tide a patient over an almost

hopeless condition for a few days, when ileo-ecceostomy or ileo colostomy or jejuno-colostomy plus crocal drainage could be performed with greater prospect of success, as the patient will be the better able to withstand this more prolonged procedure.

Until physicians and general practitioners can be educated to recognize the fact that there is but one legitimate method of treatment for acute intestinal obstruction, no matter what its cause or where situated—namely, early operation—we cannot hope for much improvement in our results.

II.—W. SAMPSON HANDLEY, M.S., F.R.C.S., Surgeon to the Middlesex Hospital

Few surgeons will deny the main thesis of Sir William Taylor's paper—that the results of treatment in acute intestinal obstruction could be greatly improved by earlier operation. Sir William declares roundly that these fatal delays are due to the ignorance and carelessness of physicians and general practitioners. I do not think that surgeons can requit themselves of blame so easily in this matter. In the first place many abdominal operations are now performed by medical practitioners whose skill and training do not qualify them for such a heavy responsibility. There are to-day too many "occasional" surgeons. Then, too, the ignorance of the subject which physicians and general practitioners often display is excusable, because their only opportunities of first-hand knowledge are derived from necropsies, where all the initial phases are lost in chaos and confusion. Surgeons, on the other hand, have opportunities at operations of tracing the early consequences of obstruction, and of educating themselves in what Sir Berkeley Moynihan has called "the pathology of the living." Has the surgeon done his duty in educating his non-surgical colleagues? Has he played his proper part in making the truth prevail? To these questions I think the answer "No" must be returned. In particular, I think the authors of surgical textbooks have failed lamentably in dealing with the symptoms of intestinal obstruction.

If diagnoses were made and operations were skilfully performed within twenty-four hours of the onset of acute obstruction it is certain that recovery would ensue in nine cases out of ten. It is here that the textbooks are so confused and deficient in the information they supply. They usually give a complete list of the signs and symptoms of obstruction, but they make little distinction between the valuable early signs and those which merely mark a lost opportunity. They do not indicate which of the signs are constant and which are inconstant. They do not explain the origin of the various signs so that the observer can form a mental picture of the critical and rapid march of events in his patient's abdomen.

This laxity of method induces the observer to wait for the development of late signs resulting from intestinal distension and early peritonitis. The early signs are few in number, and of these some are inconstant. In particular, the signs of shock and collapse may be entirely lacking if strangulation is absent. Thus, a normal pulse and temperature are frequently seen in early intestinal obstruction. There is usually no distension, and the muscle of the abdominal wall is perfectly soft, even pain and vomiting are not invariable signs.

To make an early diagnosis the observer must rely exclusively upon the presence of complete constipation—that is, cessation of the passage of flatus and faeces for a period of twenty-four hours, during which time two turpentine enemata are given. On the failure of the second enema the diagnosis must be regarded as established whatever other signs and symptoms are present or are absent. The observance of this simple rule would save many lives.

In certain forms of obstruction other early signs are present—as, for example, the local signs in strangulated hernia, or rectal haemorrhage and abdominal tumour in intussusception—but the general rule for early diagnosis is as I have stated it.

Paralytic Obstruction

The opener has dealt only with primary organic obstruction, leaving it to me to deal with a subject which has greatly interested me—namely, secondary paralytic obstruction,

which is sometimes the result of strangulation, and persists after the strangulation is relieved, or is sometimes due to the extension of peritonitis to the muscular coat of the bowel. In regard to the first variety of paralytic obstruction I would urge the importance of preventive treatment in cases where it is seen to be threatened.

Precautionary Lateral Anastomosis

There are certain cases where a loop of bowel has been released from strangulation, and where its condition appears recoverable and resection unnecessary, or forbidden by the patient's age and general condition. Unfortunately in some of these cases, though gangrene of the strangulated loop does not supervene, the loop nevertheless remains paralysed, and the patient dies of obstruction before the affected loop has recovered its peristaltic power. If in any such case it seems at all doubtful whether the bowel is paralysed I would like to urge the performance of a precautionary lateral anastomosis to short-circuit for the time being the doubtful loop. Take as a typical example the strangulation of a loop of the lower ileum by a band. Almost as a routine, except in very early cases, I would, after dividing the band, perform an ileo-ecceostomy from the ileum above the strangulated loop. I have treated thus five cases of obstruction by the appendix acting as a band, and all recovered. Of three cases of obstruction by bands or ridges crossing the ileum two recovered. The same procedure would probably often avert a fatality in cases of obstruction by a gall stone. A similar policy can be strongly recommended in cases of strangulated hernia. The intestine a few inches above the strangulated part is anastomosed to the intestine a few inches below the lower limit of strangulation. The doubtful strangulated part is left in the wound, which is not closed. In old and feeble patients I adopt this policy even if the gut is gangrenous, and I consider in such patients it is much more successful than resection and anastomosis, which may cause fatal shock. It is, of course, usually necessary to prolong the hernial incision so as to open up the abdominal cavity.

In the cases we are discussing enterostomy may prove to be a better treatment, but personally I think it can hardly improve on the results of precautionary lateral anastomosis.

Secondary Peritonitic Obstruction

We have now to consider cases of secondary peritonitic obstruction where the bowel is first acutely inflamed and then completely paralysed by the extension of the peritonitic inflammation to its muscular wall. Death in general peritonitis is usually due to obstruction, not to peritonitis as such. The obstruction is, moreover, a local one, affecting certain portions of the bowel, not a general paralysis of the whole of the bowels. "General" peritonitis is amenable to surgical treatment, even after obstruction has supervened, and the recovery rate is 75 per cent if treatment is prompt.

To understand and deal with these cases, which are most often the result of the perforation of an inflamed appendix, it is necessary to realize that unlimited peritonitis, erroneously called "general" peritonitis, almost invariably starts in the pelvis from the gravitation thither of infective fluid, and rises in the abdomen like a flood. This is true, even if the previous perforation is high in the abdomen, unless, as often happens in perforated gastric ulcers, the whole abdomen is suddenly filled with a large volume of septic material. Death generally follows before the rising flood of peritonitis has reached much above the level of the umbilicus. The peristaltic machinery of the upper half of the abdomen, though much embarrassed by distension, remains essentially intact until a very late stage.

A recognition of these facts supplies the basis of successful treatment of these cases, in which death used to be the invariable rule. The essential thing is to drain the intestine at a level above that at which its wall is paralysed. Two main methods of securing this end have emerged.

The first of these methods is that of external drainage, i.e., enterostomy, of which the pioneer was Victor Bonney, who was, I believe, the first to deal successfully with these cases, it has been largely advocated and adopted in the United States. Bonney advised the opening of the jejunum high

up, and a fortnight later, when the obstruction had subsided, he closed the fistula by resecting the jejunum and doing an end-to-end anastomosis.

The second method, which may be called the method of internal drainage, so far as the small intestine is concerned, anastomoses the upper small intestine to the large intestine. This, however, by itself is useless, for, as I have shown, the pelvic colon is also paralysed. To overcome this difficulty a temporary and self-closing caecostomy is performed.

If obstruction has come on while the peritonitis is still confined to the pelvis, the pelvic ileum and colon are the two paralysed portions of the bowel (ileus duplex), and ilico-caecostomy and caecostomy will meet the case. If obstruction comes on at a later stage, when the peritonitis has spread up to or near the level of the umbilicus, the jejunum must be anastomosed to the transverse colon, and the caecum opened as before.

It will be seen that the object aimed at in these operations is the improvisation of a complete emergency alimentary canal, providing a considerable absorptive surface, above the level of the peritoneal flood. As contrasted with an enterostomy, a considerable economy of body fluid and nutriment is achieved at a critical time. These methods were developed independently of Bonney's work as a result of my studies on the onset and spread of peritonitis, and they have proved very successful. Seven cases out of eight of ileus duplex recovered, and three out of four of apparently hopeless so-called "general" peritonitis.

It remains an unsettled question whether enterostomy or the combination of lateral anastomosis with caecostomy will be the operation of the future for these cases. The former is a simpler and quicker operation, and can be performed by an inexperienced surgeon with less strain on the patient's vital powers. The latter, with its provision for absorption and nutrition, seems a more artistic and complete solution of the problem. Recent improvements in the method of enterostomy, particularly that by which the catheter tied into the bowel is brought out through the omentum, as first practised by Dr. Wesley Long, have greatly improved the operation in that the resulting fistula is now self-closing, so that the bugbear of a second operation a fortnight later is avoided. I am inclined to think that, as thus improved, and on account of its greater simplicity, enterostomy will establish itself as the operation of choice in these cases. Personally, however, I prefer in most cases lateral anastomosis with caecostomy.

The Prevention of Peritoneal Obstruction

In any case of acute appendicitis, where more than forty-eight hours has elapsed since onset, or if pelvic involvement is suspected for any other reason, a small preliminary median incision should be made and a swab passed to the bottom of the recto-vesical pouch. If it comes up stained by pus or dirty fluid a large drainage tube should be placed in the pelvis. If, on the contrary, everything is normal, the incision should be sewn up. The appendicectomy in either event is then proceeded with in the usual way. This method ensures the detection of early pelvic infection, which would otherwise go on to a general peritonitis. I have practised it for years, and cannot too strongly urge its general adoption.

Early Diagnosis of Spreading Peritonitis

If, after an appendicectomy, vomiting returns, the pulse fails to fall to normal, flatus ceases to pass in spite of enemata and hypodermic injections of pituitrin and eserin, while the abdomen becomes distended, and perhaps rigid in its lower half, the patient's life hangs in the balance. He will not recover unless his medical adviser has sound ideas on the pathology of peritonitis, and the driving power, during the few hours of grace which remain, to insist upon the necessary operation, either an entero-colic anastomosis with caecostomy, or an enterostomy.

III.—D P D WILKIE, M Ch, F R C S,

Professor of Surgery, University of Edinburgh

It may be safely asserted that no other surgical condition commands the same compelling interest in all who practise medicine as the one which we discuss to-day. In the case of no other malady are prompt diagnosis and treatment so clearly life-saving or hesitation and delay so disastrous. No improvements in our operative procedures, or in our pre- or post-operative treatment, will ever make good the damage done by a few hours' delay in the early management of the case. A timely operation by unskilled hands and under unfavourable conditions will in the majority of cases be preferable to a delayed operation, even if performed by a surgeon of the greatest skill and experience, and in the best environment which modern conditions can supply. We must all, therefore, be familiar with the essential factors involved in such cases, in so far as they are known, that our diagnosis may be discriminating and our treatment rational.

At the outset we will distinguish four types of obstruction: (1) simple obstruction of the lumen of the gut in its continuity, (2) closed loop obstruction, (3) strangulation, (4) adynamic ileus. While in many cases two or more of these types may be combined—as, for example, when a loop of small intestine is strangulated by a band—it is still of the greatest importance that we differentiate and distinguish the essential factors involved in each type.

Simple Obstruction of the Lumen of the Bowel in its Continuity

This type is seen in its purest form where a foreign body, such as a large gall stone, blocks the intestinal lumen, or where by compression from a band or by kinking the lumen is occluded. The changes which ensue depend on the level at which the obstruction is situated. If it be in the large intestine, apart from flatulent distension, discomfort, and peristaltic activity no great disturbance need follow, and many days and even weeks may elapse before signs of grave intoxication are manifest. If the obstruction be at the lower end of the small intestine, much the same course may be anticipated, but the period between the establishment of complete obstruction and the onset of the final toxic symptoms will be shorter.

If the obstruction be high in the jejunum or at the lower end of the duodenum symptoms of urgency and of grave toxæmia appear early, and the march towards a fatal termination is rapid and progressive. Experimental and clinical evidence combine to show that two factors are active in determining the fatal issue—the one the absorption of some highly toxic product from the upper reaches of the small intestine, the other the dehydration which results from loss of body fluid into the obstructed bowel and thence by vomiting.

In our treatment of any obstruction which is either primarily of the high small intestine type or, from being primarily a low obstruction, has gradually been carried back to the upper part of the small intestine, we must counter these two factors of toxæmia and dehydration by ensuring a rapid emptying of the upper intestinal coils and by a liberal supply of fluid to make good the great dehydration. As Dixon has recently shown experimentally, there is a chloride deficiency in these cases—a further argument for a generous administration of saline solution subcutaneously.

In cases of acute duodenal or gastro-mesenteric ileus, where the third part of the duodenum is compressed by the root of the mesentery, no operative procedure is required. The passage of a stomach tube, followed by the prone position with the foot of the bed raised high, will, if promptly undertaken, almost invariably give complete relief.

In simple mechanical obstruction of the small intestine below the duodenum operative treatment is necessary, and it should be of the simplest character possible consistent with relief. In the majority of cases of simple obstruction it is, I believe, unnecessary, and it may be dangerous, to open the gut and empty it. Provided the large distended upper coils of jejunum are emptied of their content into the bowel below and an early action of the bowels is

seemed toxaemia will not unduly threaten, and the risk of peritonitis will be avoided. In the late cases, however, where the distension is extreme, and the bowel wall is sodden and oedematous, immediate evacuation of the distended coils is imperative, and a high jejunostomy by a tube an additional safeguard. Gastric lavage in all the late cases is of the first importance.

Closed Loop Obstruction

This type is seen in its simplest form in acute obstruction of the vermiform appendix, where from an impacted concretion in a stenosed portion or at a kind of closed loop results.

The importance of distinguishing in cases of acute disease of the appendix the primarily obstructive from the essentially inflammatory type is not yet sufficiently realized. I have no hesitation in including under the heading of acute intestinal obstruction a large group of acute affections of the appendix, and these are the most important because they are the most fatal if not recognized and operated on promptly. Until it is recognized and taught that a complete obstruction of the lumen of the appendix is followed by changes which, depending on the nature of its content at the moment of obstruction, are either mild or hyperacute, and in the latter case are associated with early gangrene, we shall see no further reduction in the mortality of acute appendicitis so called.

I cannot refrain from referring once more to the fact—which I have consistently taught for the past twelve years—that the sudden locking up of faecal matter within a closed loop of intestine, be it small or large intestine or be it the appendix, is followed by rapid changes which culminate in gangrene and perforation of the loop. These changes are so rapid that an appendix may be gangrenous within six hours of being obstructed, and this without any appreciable rise in the pulse or temperature of the patient.

While seen in its simplest form in the appendix, the closed loop factor is present also in various types of intestinal obstruction, in which it plays an important if subsidiary part. In a strangulated hernia a closed loop is usually formed, and should faecal matter have been present in the loop at the moment of strangulation early gangrene will result, even though the blood supply be not wholly cut off. As the small intestine is usually more or less empty, this factor does not enter seriously into the pathology of strangulations of this part of the gut. In the case of the large intestine, however, it may play a very important role, and it accounts for the fact that, in the somewhat rare cases in which a loop of large intestine is caught in a hernial aperture and completely occluded, early gangrene is the rule.

Strangulation of Intestine

We are all familiar with the striking picture of shock and collapse which follows hard on the onset of strangulation of the intestine. Whether due to volvulus, to strangulation by a band, or to a rapid intussusception, each hour of unrelieved obstruction sensibly lessens the hope of successful surgical relief. The dominating factor in this type is shock from torsion or compression of the mesentery—a form of shock which only mechanical relief by operation can hope to diminish. In the later stages peritoneal infection plays an important part in hastening the fatal issue, and dehydration from persistent vomiting contributes to reduce the patient's chance of recovery.

Our ideal in such cases must therefore be to give relief by operation at the earliest possible moment before irreparable changes in the bowel wall have set in, to combat shock and dehydration by a generous supply of fluid subcutaneously, and, where inevitable, to resect devitalized intestine. In spite of the best management of this class of case the mortality must ever be distressingly high.

Adynamic Ileus

In this group we are wont to include all cases where the obstructive symptoms depend on a lowered vitality and functional capacity in the bowel wall, no organic obstruction of the lumen being present.

Embolism or thrombosis of the mesenteric vessels is the
